Professor Chiene, of Edinburgh, wished to say a few words on this subject, on account of the large experience they had of this condition in the Edinburgh schools. He divided the cases for operation into two classes, one with sinuses and open, and one without sinuses and with unbroken surface. But practically each joint must, he said, be considered by itself. About four of these joints—the shoulder, elbow, knee, and ankle—there was no difference of opinion, the general view being that excision, with the gouge if necessary, was the proper treatment in the case of the shoulder and elbow; while in the case of the knee it was excision or amputation; and of the ankle amputation. About the wrist he was undecided. Canalization was, however, useful about the wrist.

Professor Volkmann said he spoke unwillingly, as the opinions were so irreconcilably different; that much mutual study, especially of Professor Ollier's paper, was needful before deciding. He opposed the views of Professor Chiene. He believed all scrofulous joint disease, spinæ ventosæ, etc., were tubercular, as experiments in infection and observation of the bacillus proved. In every case he had found Koch's bacilli. If that were true, then the treatment was clear. Spontaneous cure might happen, but the patient was always in danger of generalization of the condition. Further, all local recurrences were due, not to the system, but to remains of the foci left at the operation. If all were removed, as in amputation, then the wound never became infected, but, on the contrary, healed beautifully. Let them take the disease away, stick to no typical resections, but gouge and cut, and do whatever will remove disease. A joint could produce general tuberculosis, but this was rather exceptional, and he thought the generalization must depend on other and multiple foci—at least the reverse had not been proved. Professor Ollier had not mentioned the German operation. Arthrotomy was not a distinctive word. In Germany it signified wide opening of the joint, removal of the capsule and of the foci of bone till nothing remained around but healthy tissue; and then the reposition and treatment for cure by first intention, antiseptically. Such operations were often huge. They involved,

in the knee, for example, transverse division of the patella, removal of the disease, or, it might be, the front and flaps, and an operation as if for extirpation of a tumor. Professor Ollier said the operations were dangerous, but he (Volkmann) had not found them so. Professor Ollier also said that the foci could be easily left, and he (Volkmann) agreed, but thought that, in regard to the knee-joint, synovial disease was the most common.

Professor Trélat agreed that most of the affections of joints, spina ventosa, etc., were really tubercular, and he was agreed with Volkmann that the tubercular condition could heal spontaneously. He was not so clear about the diathesis. Its influence varied. It might, indeed, have no influence upon the wound, but it might certainly determine the development of other local foci.

Professor Volkmann added that out of two hundred and fifty cases of excision of the hip he had seen only five or six where the disease was not tubercular.

Professor Ollier, in his reply, said he thought the tuberculosis of children differed from that of adults. He opened largely, so as to see and remove all disease, divided the ligaments, and cut out foci. He highly esteemed the importance of the total removal of the disease, yet doubted the powers they had to remove it. He did not aim at immediate union.

Dr. Joseph W. Howe, of New York, showed a large vesical calculus which he had removed by the suprapubic method.

Dr. Lauenstein, of Hamburg, gave a demonstration in Mekuluz's operation for caries of the foot, giving eight cases with good results, four of which had been completely cured; one only required amputation afterward and one died.

Dr. Sklifossovsky, of Moscow, reported certain Russian cases.

Mr. MacEwen, of Glasgow, read a paper on

OSTEOTOMY FOR GENU VALGUM,

in which he related his experience with the supra-condyloid method.

In the discussion which followed, Professor Ogston, of Aberdeen, said he had previously operated by a method which had been called by his name, and it was, he thought, now time that some conclusions should be arrived at concerning the various existing methods of operating for genu valgum. There had now been sufficient time given and sufficient experience of these operations to enable surgeons to arrive at some definite understanding regarding them. He had himself operated by MacEwen's method a considerable number of times, and in such a way as to be enabled to form a definite opinion on comparison of these two methods. He had operated on one side of the body by his own method, and on the other side by MacEwen's operation exactly as described by its author; and he was forced to come to the conclusion that, for simplicity and good results, MacEwen's operation was better than those he had himself advocated. He had not for himself altogether given up his own operation, chiefly because when one got into the habit of doing a particular operation, one did not like to throw it overboard altogether, being so familiar with it. But he had for some years past told his students that MacEwen's operation was the best, and he wished to make to that meeting of the congress a similar announcement. He would advise every person who wished to osteotomize for genu valgum to adopt it in preference to his own. Referring, however, to the statistics which Professor MacEwen had laid before the congress, he said that he had found the German surgeons, even those who at first had adopted his own operation enthusiastically, had now given it up in favor of MacEwen's, as the better and simpler operation of the two. That was another reason for adopting it himself.

Professor Chiene, of Edinburgh, said that after what he had heard, he thought it right to state that, although he could not go to the length of Professor Ogston in throwing up his own operation entirely, still he would give MacEwen's operation a fair trial on his return to Edinburgh. He thought that in all likelihood he would be able to report as favorably as Professor Ogston had done concerning it. It was, however, after all, the profession that were the judges of the merits and demerits of these operations, and they had seen from the statistics which had been given in that section, and he also knew it to be the fact, that his own operation, whatever he might think of it himself, had not commended itself to the profession generally.

Professor Schede, of Hamburg, said he had put forward an operation for genu valgum of the tibia which had gone by his name, and he still practised it in some cases. But in practising that operation he had not done so by old ways, especially so often as he had previously done, but had substituted for his own the operation of MacEwen, and had by that method obtained excellent results. He thought in many instances that the tibia was involved, and he therefore in these cases performed his own operation. But there was no doubt that there was a large number of pathological points showing that the femur alone was involved in a great many cases, and in some equally so with the tibia. He differed from MacEwen in this respect that, in doing his operation, he did not use several chisels, as was recommended in MacEwen's work on osteotomy, but only one, thinking the withdrawal of the instrument from the wound was a serious matter, inasmuch as it sometimes led to a disturbance of the parts, and to a difficulty of reintroduction of the instrument. But, along with all German surgeons, he accepted MacEwen's operations.

Mr. Bryant, of London, said he thought the section, after hearing what had been said by these three great men, would scarcely find it necessary to discuss further the relative value of these operations. They would all agree that MacEwen's operation had been proven by the statistics adduced, and also by the fact that the authors of the other methods had now practically given them up. He must say for himself that he had used MacEwen's operation many times with very great success, and it was gaining ground where previously Ogston's operation had been practised. He was sure the section would endorse what had been said about MacEwen's operation being the best one, but he could not sit down without expressing the very great pleasure he felt at the manner in which the other gentlemen had given up what he might call their pet operations. Professor Ogston had done this with the greatest possible grace, and he (Mr. Bryant) was sure the section would award him and the others a vote of thanks for the manner in which they had acted.

Dr. V. Robin, of Lyons, next read a paper "On a New and Perfected Method of Osteoclasis for Genu Valgum," with eighty photographs of patients operated on after this new system.

Mr. W. Adams, of London, read a paper demonstrating a series of photographs taken from cases of

DUPUYTREN'S FINGER CONTRACTION.

He took occasion to correct what he said was in the books, the anatomically imperfect description of the fascia and its relation to the tendons of the hands, with a special view to the pathology of this affection. His own operation for the cure of the condition, which he described at length, he designated as a happy combination of the tenotomy of Dupuytren first described in 1831 with the subcutaneous surgery of Stromeyer; its object being to deal with the fascia at fault, as well as the tendons. As to the pathology of the condition he still adhered to his own view that it essentially depended on a chronic gouty thickening of the fascia.

In answer to a question as to the return of the condition after operation, he said that in his own cases he had found no severe ones of return and had never seen much

tendency to it. The great majority remained free from it for life.

THE LISTERIAN ANTISEPTIC TREATMENT.

In the absence of Professor Sir J. Lister, of London, who was to have opened the discussion of the present form of his treatment, PROFESSOR ESMARCH introduced the subject with a paper. He began by expressing regret at the absence of Lister, the illustrious master and teacher of them all. He then went on to describe the method of treatment now followed in his own clinique. The aim was the avoidance of suppuration in any case, and the leaving of the wound undisturbed. This was best done by a permanent dressing preventing the entrance of germs. The postulates were, first, exact hæmostasis; second, the avoidance of cavities in the interior of the wounds; third, drainage, artificial ischæmia, application of multitudes of catgut ligatures on great and small vessels, and bandage applied before removal of tourniquet, support of all the deep parts by sutures, curling in the edges of the skin, and pressure. The drainage-tube, as preventing healing, was not now used by him, but openings were left for escape of exudation.

Asepsis was minutely studied. The bandage strips were sterilized by dry heat and sublimate. The spray was used only *before* operation, so as to disinfect the air in the room. During one operation distilled water with salt only of specific gravity of the blood, was used for irrigation, but at the end sublimate was employed.

Occasionally other antiseptics, as iodoform, were used. For bandage material, loose, absorbent, soft matter was needed. Peat was useful in pillows (no Mackintosh), dipped in carbolic lotion. Then immobilization of the parts was obtained by glass splints till healing by first intention occured. The latter took from eight to ten or fourteen days to five or six weeks after operations.

DR. MOSTIG-MOORHOF advocated iodoform treatment of wounds, and said he operated with no other antiseptic. He used cold water during operations. There was no irritation and certain asepsis. Iodoform prevented transudation of the white blood-cells. He narrated a case of traumatic septic gangrene extending above the knee, where yet the knee-joint was found aseptic at the post-mortem examination. Iodoform, also, was a substance that diminished pain.

DR. SCHEDE said that the principles of antiseptics remained unaltered, though the methods had changed. After his training in Halle, when called to Berlin, he found Lister's method perfect in its results. But on succeeding to Marten, at Hamburg, he had never had perfect success with Listerism; he was now unable quite to exclude accidental wound disease from his cases. The hospital was old, and in many respects undesirably arranged and situated. He tried iodoform without good results. On the reports as to the substance he had resolved to try the sublimate dressing, and now, after experience, had got with it brilliant results. Erysipelas at once disappeared, not one case had since occurred under the dressing in his clinique. There was neither septicæmia, pyæmia, nor irritation. Wounds had occurred; but they were dry, and showed a great tendency to heal by first intention. His impression was that it was equalled by no other plan. He now used a solution of 1 to 500, and had no case of poisoning with these strengths. Sometimes, however, there was tenesmus of the rectum. Children especially tolerated the sublimate wonderfully. In the final dressing he tried to keep everything dry.

DR. MIKULICZ did not agree with either Moorhof or Schede. In his clinique, which was much worse than Schede's, he had had no erysipelas with iodoform. But iodoform could not be used alone. Other soluble substances must be applied where its insolubility prevents its fulfilling the indications. He disinfected with carbolic or sublimate solution, and had no spray. In the vagina, etc., he plugged the canal with iodoform gauze; in rectum, stitched one side and the upper end of the sphincter, and had no drain, even where the peritoneum was opened. Poisoning occurred only from excessive use.

PROFESSOR NEUDÖRFER, of Vienna, said the aim of antiseptic surgeons was the same, but the methods varied, and must of necessity vary, almost to infinity. Our knowledge was limited; they knew that decompositions occurred, but nothing as to how, how far, or how intensely they did so. Each surgeon was satisfied with his own plans and really got good results. But statistics were not of much value. They must study rather in the direction of sepsis. Sepsis needed water; therefore he never used water in his wound treatment. He used no sponges, but a dry towel crumpled together to wipe up the blood and wring it out. The serum of the blood was a matter that should be studied; oxidation and deoxidation were important processes. Therefore he used in his wounds peroxide of hydrogen and had found singularly good results.

PROFESSOR BUCHANAN, of Glasgow, said the discussion of antiseptics without Lister was like the play of Hamlet with the Prince of Denmark left out. As a representative of Scotland, the home of antiseptic surgery, a colleague of Lister, and one who had witnessed his earliest results, he wished to contribute a few words to the discussion. He agreed that the principles of antiseptics were always the same, though the methods might vary; and he described the method now employed in Glasgow.

DR. SCHELKLEY, of America, said the tendency to disease, sepsis, etc., was different in different races. His practice had been in the tropics. First he used thorough Listerism, but never got healing by first intention, but always slight surface sloughing and healing by second intention; yet no pus and no fever. He then changed his plan, ceased to spray, and irrigated during the operation with salicylic acid or sublimate, and iodoform dressings or boric lint. Salicylic and iodoform gave the best results, yet he did not get "first intention."

PROFESSOR KOEBERLÉ, of Strassburg, said that since 1884 he had used only linen to wipe his wounds, and had had no case of erysipelas among his operations since then. He claimed to have better results than Schede; even his ovariotomies were all cured.

PROFESSOR PLUM said that the Danish surgeons agreed entirely with the German, but he was prevented from agreeing with Esmarch's plan on account of its cost. The chief antiseptics were soap and brush, and by simple means much might be done.

PROFESSOR TRÉLAT said he had, three years ago, laid down the following lines: Make the wound of a form suitable for healing by first intention, and perfectly adapted. Leave no foreign body in the wound, either mechanical or septic. Antiseptics did not exist in some countries—not on the top of Chimborazo—and half-educated Americans did wondrous operations on negroes. The principles of antiseptics were not altered; the practice was being perfected. He pointed out the incomparable merit of Lister, who had given them the principles; whatever the methods might become was of little importance. He (Trélat) used the iodoform gauze—deeply as plugs, and superficially as required; and made a large cushion pressed with elastic bandages to the wound, changing the dressings on the fifteenth day.

DR. MOSTIG-MOORHOF challenged Mikulicz to say that he had ever tried a thorough iodoform dressing; and if not, whence he knew that iodoform required other antiseptics to supplement its use. At the time that Schede had tried iodoform there was an epidemic of erysipelas all over Europe, and if he would try it now he would get better results.

PROFESSOR PLUM closed the debate with a compliment to Lister, which was received with great applause.

PHELPS' OPERATION FOR CLUB-FOOT.

DR. A. M. PHELPS, of Chateaugay, N. Y., detailed cases and showed photographs of club-foot which he had treated by a new operation, consisting of tenotomy

of the tendo Achillis, incision of the sole of the foot opposite Chopart's joint, cutting of the tendons and tissues down to the bone, leaving only the external plantar artery and nerve. Afterward the foot was fixed in position by wire hooks of adhesive plaster laced together. It had been performed in children five years of age or thereabouts.

Professor Studegard, of Copenhagen, read a paper on

THE TREATMENT OF STRICTURES OF THE ŒSOPHAGUS.

He had, he said, taken great interest in this question and in the statistics of it. Where dilatation failed, gastrotomy, he thought, might be had recourse to, and the stricture dilated even from that. In his practice in cavernous stricture one case had survived for seven, one for six, and one for five months after the operation. In four of stricture from cicatrix, two died and two survived. In pressing cases, where the gastrotomy could not be performed in two stages on account of nutrition of the patient, he thought that a minute opening should be made at once, and close sutures should be adopted. Langenbach made a capillary puncture for this purpose. He recommended, as a general rule, that the operation should be done in one sitting, the sutures not including mucous membrane. The latter was so loose that there was no fear of including it. He referred to a patient upon whom he had operated for stricture of the œsophagus, probably superficial, two and a half years ago, who now fed himself by a drainage-tube doubly bevelled at the point, and was in a perfect state of health.

Professor Hjorth, of Christiania, adduced a case of stricture from contraction after swallowing an alkali. No sound could be passed below the cricoid cartilage, and there was difficult swallowing by slow efforts. Gastrotomy was performed, with œsophageal catheterism and electrolysis applied at the part and a specially constructed bougie. The positive pole was on the right side of the neck; first five, then ten, and finally fifteen cells were applied, and after an hour the bougie went through suddenly. Stricture three ctm. long. No bad results followed, and a repetition of procedure was gone through twelve days later. The patient could now swallow, and soon flesh and solids were swallowed, and a No. 19 bougie (Charrière) went through from below and above. The largest bougies now passed, and the patient was well nourished. A fortnight later he (Professor Hjorth) closed the gastric fistula by a vivification operation and a bridge transplanted by glissement. For such catheterism the cardiac opening must be large enough to admit the finger. The cardiac orifice was found without much difficulty, especially if a curved staff bougie was first passed up. To cure the gastric juice digestion of the wound after the first operation, he found the bismuth dressing valuable. He therefore advised gastrotomy and treatment from below for œsophageal cicatricial stricture, and secondly the use of electrolysis.

Professor Verneuil once saw a stricture from alcohol. There was no malignancy and no caustics in the case, alcohol being the sole cause of the condition. He approved of the conclusion of the operation in one sitting. He sutured closely and opened very minutely, about the size of a No. 10 English catheter, and nothing escaped. The sound was lodged and stitched in, and no harm ever resulted, the antiseptic dressing being applied. So long as the patients could swallow, and a fine sound be passed, dilatation was the proper treatment, especially by the permanent lodgment of a red rubber sound; and the patients could be brought to go about all their affairs with this sound in, it being withdrawn when they wished to swallow.

Professor Schönborn warned the section against gastrotomy when the patient had bronchial symptoms, as these probably indicated the involvement of a bronchus. He approved of the operation being done in two sittings. The piece of stomach fixed in the wound had, however, in some of his cases, become spontaneously perforated from deficient nutrition.

M. Petit, of Paris, gave some very elaborate statistical details as to 155 operations, with two per cent. cures and twenty-seven per cent. deaths. This was before antiseptics were employed.

Mr. Thornton, of London, spoke of one case from hair swallowing. He proceeded to make a median incision, opening the stomach by transfixion, the peritoneum being protected by packed carbolized sponges. Removal of the mass was affected, and the stomach sutures were made in a double row, deep and superficial. There was subsequently right parotitis and incision, but no pus. Left parotitis was treated by belladonna cataplasms. He found a sponge had been left in the peritoneum, chiefly by localized pain and counting the sponges. On opening the abdomen to remove the sponge he found the stomach wound healed.

Mr. Bryant, of London, said he found one row of sutures enough. He described the minute opening of the stomach adopted by him. His colleagues in Guy's Hospital had, in six operations, used clamping, drawing out the stomach by two rubber-shield forceps, and used no sutures. One patient subsequently married and had a child. In her case, two and a half years after the operation, she suddenly found she could swallow liquids and solids, such as bread, fish, and minced meat. She still had the fistula, and Mr. Bryant had advised her to leave it alone, as she was quite dry, even after a large meal.

Professor Sklifforoswsky advised œsophagotomy, and subsequent dilatation through the wound.

Professor Hjort said fifteen elements were necessary in electrolysis.

M. Ollier advised, in preference to operations, wherever possible, the use of the minutest whalebone bougies, one-half mm. in diameter, and the treatment on the principle which Syme, of Edinburgh, had enunciated for the urethra, viz., that no case was impermeable. He admitted this was sometimes excessively difficult, but it was always possible, and then dilatation was often extremely easy.

SURGICAL ANÆSTHESIA.

Dr. O. Wanscher, of Copenhagen, in a paper on this subject, dealt with anæsthesia by rectal insufflation of ether vapor. Pirigoff's first attempts were not attended with good results. Duping and others tried the method, but it fell into disuse. Two years ago he (Dr. Wanscher) again took up the subject, and his experience had convinced him that it should be revived, especially in aid of other methods, so as to improve the respiratory organs. There must be preliminary cleansing of the rectum, and insufflation of the vapor through a warmed reservoir. He narrated cases.

Dr. Jennings, of London, said that unless the epiglottis were drawn forward by a suture put through it, it fell down during respiration, and unless this were done tracheotomy should not be performed. In experiments on dogs with chloroform, the epiglottis was secured forward, the tongue drawn forward, and the chloroform administered until the heart stopped, and more was then given until artificial respiration failed to restore its action. Then the jugular vein was opened, a canula put in toward the heart side, and a saline fluid injected, while bleeding from the peripheral end was allowed to go on. The dog recovered, but, from the amount of blood lost, was likely to die. He then injected the quantity of blood corresponding to the excess of blood lost, and the animal recovered.

MASSAGE.

Dr. Tubelerdowsky, of Berlin, in a paper on this subject, said he knew a lady in Berlin who took a pain in her knee every time her husband had an attack of angina pectoris.

Dr. David Prince, of Jacksonville, Ill., read a paper

upon "Palatoplasty with a New Instrument," and demonstrated his needles.

Professor Moore, of Rochester, N. Y., read a communication on

LUXATION OF THE ULNA IN CONNECTION WITH COLLES' FRACTURE.

In this fracture, he said, there was also an accompanying displacement of the lower end of the radius. After the radius gave way the attachments of the triangular cartilage and internal lateral ligament, acting on the styloid process, broke it off, or were themselves torn. In continuation of the force the ulna was shot on, and, penetrating the fascia and skin, might become compound. He advised reposition under chloroform, with subcutaneous division, if needful, in recent cases. In old standing cases he resected the lower end of the ulna. His method of reduction was by flexion and pronation over the knee, and he retained it with finger and thumb. He then laid a slender splint and rolled bandage, three-fourths of an inch in diameter, and fixed it by a strip of plaster drawn up as tightly as possible. The hand was allowed to drop, and a sling of bandage the length of the plaster strap put over the spot.

Dr. Oscar Wanscher, of Copenhagen, read a paper on the

TORSION OF LARGE ARTERIES NEAR THEIR BIFURCATION.

He had, he said, had no cases of his own, but he had experimented on animals on torsion and refoulement, and he demonstrated the results.

Professor Plum, assuming the chair, thanked the audience, the presidents, the speakers, and the bureau, and bade all *au revoir à Washington en* 1887.

(To be continued.)

Correspondence.

SHALL ARMY SURGEONS PRACTISE OUTSIDE THEIR POSTS?

To the Editor of The Medical Record.

Sir: The accusation of unfairness from one who hides himself behind the wand of the god of dissimulation, etc., falls flat; and the letter he writes to prove it fails lamentably. The mental obtuseness which prevented my seeing things as some medical officers see them, still prevents me from acknowledging the fairness of this accusation. The "extract from a letter" simply begs the question.

I shall be more than glad, if it can be shown that any statement in my letter is not strictly just and fair. The "extract" simply proves that the custom of which I complain dates farther back than I had supposed, from what had been told me by "officers and gentlemen" in the army. That does not make the custom any more proper, nor does it prove any statement of mine unfair. I see nothing in this "extract" to convince any one that it is fair and honorable for an adequately salaried army surgeon to employ most of his time in practising outside his post, when by so doing he is necessarily brought into competition with physicians who have not the advantage of an assured and regular income outside of their practice. I must reiterate, that it is unfair and unjust competition; and no amount of "extract" is going to alter that FACT.

The argument that it would be ungracious to deprive a suffering public from consulting army surgeons looks pretty, but is unmitigated bosh. If that will apply to any one branch of the service, it must apply logically to all others. Imagine a suffering public seeking legal advice from the law officers of the Government in ordinary legal matters. Imagine also the frame of mind of civil attorneys-at-law *et al.* under such circumstances.

With all due respect I would submit that the average army surgeon who does outside practice, is actuated more by a strong desire for the accruing fees than by any purpose of "becoming familiar with disease under all circumstances," etc., however beautiful and lofty such a purpose might be. I am of the opinion, rather, that the purpose kept steadily in view is mainly in regard to that "which relates exclusively to (the army surgeon's) private interests."

Notwithstanding the "extract from a letter" with its specious argument, I am still of the belief that it is not, and has not been, the general custom for army surgeons to do or seek outside practice except under exceptional circumstances, which do not obtain here. If at small posts "it has been found much more satisfactory, for military reasons, to have the duties of post surgeons performed by a regular medical officer," it would be equally satisfactory, for civil reasons, that he should confine himself to his appointed duties, and not encroach on what I claim is no legitimate field for operation. Stripped of all sentiment, the army surgeon is a public servant and is paid for his services. If he has plenty of time to devote to outside practice, then he is paid too much for what little service he does render, and therefore receives more than he is justly entitled to; or if it is proper to practise in the region about him, *to the end that he may not grow rusty and thereby inflict injury on the service generally*, then it is not proper for him to receive fees for so doing, since by his own admission he is only striving to maintain his standard of excellence.

The attempt in this "extract" to throw upon us physicians the odium of trying to prevent army surgeons from familiarizing themselves with the "maladies prevailing through the country and among citizens generally," will fail simply because it does not contain the elements of common-sense.

It will require more proof than is adduced by "Caduceus" to convince any one that practising outside of posts by army surgeons *for pay* is proper, while they are on full salary from the Government.

Very truly yours,

John G. Stanton, M.D.

New London, August 20, 1884.

OBESITY AND THE SEXUAL FUNCTION.

To the Editor of The Medical Record.

Sir: In your issue of this date, at the bottom of the first column of page 183, I notice an explanation of the fact that women are more subject to obesity than men which strikes me as very odd. It is contained in these words: "The lesser activity of their sexual life." I feel that I am not alone in failing to understand the meaning of this phrase. You surely do not mean that men copulate more frequently than women; and yet what else can you mean? Yours respectfully,

Youthful.

August 16, 1884.

[We refer to the generally accepted fact that women, as a rule, experience sexual feelings less intensely and less frequently than men, and to the fact that the mass of respectable women masturbate less and have intercourse less often than men.—Ed.]

The Rights of a Defendant on Trial for Rape.—A court in a Western State has recently held that, upon the trial of a person indicted for rape upon a female child, evidence is admissible of the answers given by the girl, two or three days after the alleged injury, to the questions of her mother, induced by the girl's singular demeanor. A hypothetical question put to a physician, whether in his opinion the facts assumed would constitute rape, is altogether improper, being a demand for his legal instead of his medical knowledge. Yet, if he gives a correct answer, the impropriety of the question is no ground for a new trial.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 23 to August 30, 1884.

HEAD, JOHN F., Colonel and Surgeon. Granted leave of absence for four months. S. O. 201, A. G. O., August 27, 1884.

WOODHULL, A. A., Major and Surgeon. Detailed as member of Medical Examining Board at U. S. Military Academy, West Point, N. Y., vice Captain R. H. White, relieved. Upon adjournment of the Board to return to his proper station. S. O. 201, C. S., A. G. O.

LIPPINCOTT, HENRY. Promoted Major and Surgeon, to rank from August 17, 1884, vice Woodward, deceased.

BARTHOLF, J. H., Captain and Assistant Surgeon. Relieved from duty in Department of the Columbia, and to report in person to Commanding General, Department of Texas, for assignment to duty. S. O. 199, A. G. O., August 25, 1884.

FINLEY, J. A., Captain and Assistant Surgeon. The leave of absence granted him in S. O. 91, C. S., Department of Texas, extended two months. S. O. 198, A. G. O., August 23, 1884.

TAYLOR, M. E., Captain and Assistant Surgeon. Granted leave of absence for four months, to take effect on arrival of a Medical Officer at David's Island, N. Y., to replace him. S. O. 200, A. G. O., August 26, 1884.

GIBSON, R. J., First Lieutenant and Assistant Surgeon. Relieved from duty in Department of the Missouri and ordered to Department of California for duty. S. O. 202, A. G. O., August 28, 1884.

DIETZ, WILLIAM D., First Lieutenant and Assistant Surgeon. Relieved from duty at the Military Academy, West Point, N. Y., and ordered to the Department of the Missouri for duty. S. O. 202, A. G. O., August 28, 1884.

MCCAW, WALTER D. Appointed Assistant Surgeon, with rank of First Lieutenant, to date from August 20, 1884.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending August 30, 1884:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.								
August 23, 1884	0	26	32	1	50	22	0	0
August 30, 1884	0	34	28	5	38	30	0	1
Deaths.								
August 23, 1884	1	16	5	1	10	11	0	1
August 30, 1884	0	11	5	4	12	17	0	1

STIGMATA MAIDIS IN GONORRHŒA.—Dr. Bennett says that he has had unusual success in the treatment of gonorrhœa by fluid extract of corn silk (stigmata maidis). To him the treatment was quite novel, while it has been a great comfort to the patients, who were entirely relieved within a week, and very often in three days. He depended alone upon the corn silk, and of course made no error in attributing success to that drug. A half-teaspoonful to a teaspoonful of the fluid extract three times a day will prove effectual in male or female.—*Therapeutic Gazette.*

"DEATH owing to visitation of Providence under suspicious circumstances," is a coroner's verdict in Munster.

A CURIOUS FREAK OF NATURE.—Dr. Marvin, Resident Physician of the Saginaw Hospital, East Saginaw, Mich., sends us the account of a very curious occurrence. "A few days ago," he writes, "while Dr. Ross, Surgeon-in-Chief of Saginaw Hospital, was attending a case of obstetrics, he met with a peculiar freak of nature. After the child was delivered and the umbilical cord severed, he found a shred of membrane passing into the child's mouth and seemingly fast there; on following it to the vulva on the mother he found it was attached internally. He severed the shred, and by further examination found that it passed into the child's mouth behind the soft palate and out through the left nostril, and was tied in a slip-knot around the part that entered the mouth. After the secundines were removed the other end was followed to its attachment, which was on the placenta near the umbilical cord. It was there found it started in a shred about three fingers in width, and diminished until it was about one-fourth of an inch wide where it entered the mouth; from that point it kept up a uniform width to its end." Dr. Marvin encloses to us the specimen, so that we can verify his description.

THE QUESTION OF THE FLORIDA CLIMATE.—Dr. R. A. Lancaster, of Gainesville, Fla., writes us a letter in defence of the Gainesville and the Florida climate, supplementing Dr. Bradner's letter. After some rather personal criticism of Dr. Boyland's views, he concludes: "That many consumptives do die in Florida, however, all will admit, and I think their physicians are to be censured for sending them away from the comforts of home when they are so evidently beyond all hope of recovery; but that the lives of many consumptives have been prolonged, and many catarrhs and cases of bronchitis of long standing have been permanently cured, is a fact that no honest observer will deny. This 'Question of the Florida Climate' is one of paramount interest, not only to the profession, but to countless invalids throughout the United States. Now, how can the truth be known when there are so many conflicting statements regarding it? Would it not be a capital idea for the American Medical Association to appoint a commission of unprejudiced and uninterested men, to come and spend some months in Florida and make an official report of what facts could be gathered, both as to Florida in general and as to particular localities? No doubt physicians of note could be found who, on account of catarrhs, bronchitis, etc., would be glad to spend a few months in our genial clime. Will not Dr. John T. Metcalf, of New York, favor the readers of THE MEDICAL RECORD with his views of Florida as a health resort? I am told that he spent several months in and around Gainesville some years ago."

THE REMOVAL OF BODIES FROM ONE BURYING-GROUND TO ANOTHER.—The question of the right to remove the body of a person from one resting-place to another is frequently up before the courts for determination; but an unusually curious instance occurred recently in Brooklyn. A gentleman named Gardiner H. Wolcott, residing in Astoria, died in 1881, and was buried in Greenwood Cemetery. He was supposed to be intestate, and his property, amounting to about forty thousand dollars, was divided up between his heirs. Not long since a will was discovered directing that his body should be buried in Greendale Cemetery, Meadville, Pa. An application was then made to the Surrogate for a sufficient allowance to carry out this wish, which was opposed by the relatives of the deceased man, who would be obliged to contribute their respective shares to meet the expense. The decision of the Surrogate was to the effect that, as the estate was divided up, and the relatives opposed the reinterment, the body must remain where it was.

SUCCESSFUL ŒSOPHAGOTOMY FOR THE REMOVAL OF FOREIGN BODIES.

BY LEROY McLEAN, M.D.,

SURGEON TO TROY HOSPITAL, TROY, N. Y.

IN the number of this journal for April 29, 1876, I recorded two cases of œsophagotomy. To those I have now to add three others, making in all five œsophagotomies done for the removal of foreign bodies. A summary of the two cases referred to will, I think, be of interest in connection with those I am about to report.

CASE I. *Tooth-plate swallowed during sleep; œsophagotomy; recovery.*—Mr. C——, of West Troy, N. Y., during sleep swallowed a gold tooth-plate with one central incisor attached. The plate, which was crescent-shaped, measured from point to point one and a half inch, and one-half inch from outer to inner edge. On the outer edge were eight sharp and irregular projections which fitted between the teeth and held the plate in position (see Fig. 1).

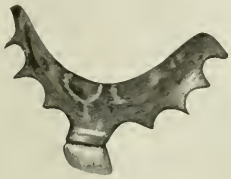

FIG. 1.[1]

I saw him three days after the accident, after many attempts to dislodge had been made, and after the conclusion was reached that the foreign body had been pushed into the stomach. He was suffering intense pain; neck swollen and inflamed; all nourishment regurgitated; *voice faint and husky*. The foreign body could be easily grasped with œsophageal forceps, but the application of much force to dislodge it was deemed impracticable owing to the many points of resistance which the sharp projections on it offered. The operation was performed the following day. Incision on the left side three inches long, extending from top of thyroid cartilage downward, midway between it and the sterno-cleido-mastoid. Upon reaching the œsophagus a large-sized lithotomy staff was introduced through the mouth and the œsophagus pushed forward, into which a longitudinal incision was made, the finger introduced, and the foreign body with much difficulty removed from its resting-place just below the cricoid cartilage.

The wound in œsophagus was not closed. For the first day enemata of beef-tea were given, and bits of ice allowed to dissolve in the mouth. After twenty-four hours was allowed to drink milk, one-third escaping from wound. Third day, could swallow fluids readily, very little escaping. Fourth day, ate an oyster, swallowing it without experiencing pain. Fifth day, sat up dressed; could readily swallow soft solids; no discharge of fluids by wound. Sixth day, was out of doors. Twentieth day, resumed business; wound entirely healed.[1]

CASE II. *Tooth-plate impacted in cardiac portion of œsophagus eleven months, causing stricture; œsophagotomy; recovery.*—Mr. P——, of Gansevoort, N. Y., while at dinner dislodged four upper false teeth attached to a silver plate by striking them with his fork. They were involuntarily swallowed, passing into the œsophagus. The plate was one and a half inch broad, by about one inch in depth from front to rear (see Fig. 2).

FIG. 2.

His physician was summoned, but did not arrive until evening, when an attempt was made to reach the teeth. Instruments were passed down over ten inches, but failed to give any indications of touching them, leaving the inference that they might have passed into the stomach. This was strengthened by a sharp and severe pain which he felt in the region of the stomach. Within a fortnight most of the pain and soreness had passed away, and he was enabled to swallow liquids without difficulty and most kinds of food with varying success. He frequently passed weeks without any marked inconvenience; at times, however, there would be unusual distress in the chest, or a return of the difficulty of swallowing. He first consulted me six months after the accident, when I found that the teeth were still in the œsophagus, eleven and a half inches from front of upper jaw while the head was thrown back. An operation was advised: this he wished to delay, as he was not suffering essentially. For five months nothing was done, when, as he was having great difficulty in swallowing, I was consulted. An operation was again advised, to which he assented. *This was eleven months and seven days from date of accident.* The incision was made on the left side of the neck, commencing opposite the thyroid cartilage and reaching to the sternum. The œsophagus was reached without difficulty, and an opening large enough to admit the finger made in it as near the sternum as possible. Passing a finger through the incision and downward a constriction was felt, below which lay the foreign body quite out of reach. A polypus forceps was then directed by the finger down upon the plate, which was soon brought up, without the teeth, however, they having become detached in the effort at removal. The teeth were voided by the rectum some days after. Wound not closed. He began to take liquid nourishment by mouth on the third day. On the thirteenth day walked out of doors. Owing to a troublesome cough the wound did not close until the sixth week, at which time he resumed his business. He rapidly regained his health, which at this writing is still excellent.

CASE III. *An infant swallows a penny; œsophagotomy; recovery.*—E. F——, aged sixteen months, residing in Lansingburg, N. Y., while playing with an ordinary nickel cent, put it into his mouth and swallowed it. The family physician, Dr. Capron, who was immediately summoned, after carefully examining the child concluded that the penny had passed into the stomach, and directed that the stools be watched. On the 27th he was again called and found that the child was regurgitating most of the food taken. A probang, with sponge attached at end, was passed to the stomach. This for a time seemed to afford relief. On the 28th and 29th an olive-pointed probang was passed with no effect, the food being persistently regurgitated. I was called to the case on the 30th. The patient was then refusing absolutely to take nourishment, and was beginning to suffer from want of food. The olive-pointed and sponge probang was again introduced, but as they gave no indication of contact with the foreign body, a metallic catheter guide (Otis')

[1] He is, at this date (July, 1884) enjoying good health.

was passed. A distinct click was heard as it was moved up and down within the œsophagus. The sponge probang was again tried but the penny could not be dislodged, the instrument passing beyond it at each introduction. The point of impaction seemed to be at a point on a level with the clavicle. On the 31st another effort was made with a like result. As the child was becoming rapidly reduced from inanition, an immediate operation was decided upon.

With the assistance of Dr. Schuyler, Dr. Capron, and the Drs. Bucklin, of Lansingburg, the operation was done at 11 A.M. The incision was made upon the left side. The dissection was exceedingly slow and tedious, owing to the minute anatomy of the patient. The œsophagus was finally reached without tying a vessel. A small laryngeal brush-holder, to which was attached an ivory tip, was substituted for the lithotomy staff in pushing the œsophagus forward; with this exception, the various steps of the operation did not differ from those in previous cases. The penny (see Fig. 3) was found where it had been located previous to the operation, *i.e.*, on a level with the clavicle. It was removed with a Gross polypus forceps. The wound was not closed. The recovery was rapid and complete. No impairment of voice.

Fig. 3.

Case IV. *A tooth-plate swallowed while asleep; removed by œsophagotomy twelve years after; death.*—J. F——, aged thirty-six, of Albany, in August, 1869, swallowed while asleep a tooth-plate with two central incisors attached. The plate, which was of rubber, measured one and a half inch in width, and one and one-fourth from front to rear (see Fig. 4).

Fig. 4.

Medical aid was sought at once, and efforts made at removal. It was finally concluded that the plate had passed into the stomach, as he felt greatly relieved after the introduction of the instruments. He was then removed to the city hospital, and kept under observation for some days; but as nothing resulted, and as he felt perfectly well, he left the institution and the city to make his home in Omaha. For ten years he suffered no pain, and but little inconvenience, and then only when large pieces of food were swallowed. During the next two years, however, the difficulty in deglutition greatly increased, until it was almost impossible to swallow even fluids. Believing that he could not long survive this condition, he concluded to seek medical advice. Getting no encouragement in the West from physicians whom he consulted, he came to Troy seeking the counsel of his relatives.

I saw him then for the first time. *This was twelve years and two months from time of accident.* He was greatly emaciated. Most of the liquid nourishment (the only form in which it could be swallowed) taken was immediately regurgitated. His face bore an anxious expression; was very solicitous as to the immediate future, and begged that something might be done for his relief.

Upon passing an olive-pointed probang, an impassable obstruction was found eleven inches from incisor teeth. As the instrument gave no evidence of contact by sound, it was inferred that the foreign body had become encysted, and all efforts at removal in that direction were abandoned. The operation was done at the Troy Hospital, November 2, 1881, with the assistance of Drs. Schuyler and Nichols, and other members of the hospital staff. Owing to his extreme emaciation the œsophagus was easily and quickly reached, and opened at the lowest possible point. By introducing the finger it was possible to reach the obstruction. It was then found that, with the exception of a tip of one of the wings, the plate was completely encysted. By the aid of the finger and an œsophageal forceps, the plate, after prolonged effort, was lifted from its resting-place. A single suture was introduced at upper end of external wound, otherwise it was left open as in previous cases. A nutritive enema with brandy was administered and the patient put to bed. Then for the first time a peculiar wheezy and labored respiration, and slight emphysema in the wound, were noticed. He did not rally well; though he was enabled to swallow considerable milk and brandy (by holding the edges of the wound together) and retain the enemata, he gradually sank. The emphysema increased, the respiration became more embarrassed, and the exhaustion more pronounced, until the time of his death, which occurred forty-eight hours after operation.

The autopsy was made twelve hours after death. The wound was found to be healthy. There was no evidence of inflammation of parts at the point of impaction of the plate. Search was made for the cause of the emphysema which appeared immediately after the operation. It was thought that during the removal of the plate from its surroundings a slight perforation of the trachea had occurred, but the most careful search revealed nothing, however, to confirm this belief.

The conclusion finally reached was, that during a violent fit of coughing at the time of the administration of the anæsthetic the expiratory effort ruptured some of the air-vesicles, the air first escaping into the cellular tissue between the lobules of the lung, then into the mediastinum, and from thence to the root of the neck. The presence of dyspnœa after the operation would seem to strengthen this belief. He undoubtedly died of exhaustion.

Case V. *Tooth-plate swallowed while asleep; œsophagotomy; recovery.*—Mr. K——, aged thirty-eight, residing in East Greenbush, N. Y., on April 9, 1884, retired at 12.30 A.M. About 3 A.M. he was suddenly awakened by a sharp burning pain in his throat. Springing from his bed he hastily swallowed a glass of water and felt relieved. Retiring again, the pain soon returned with increased violence.

He then for the first time discovered that his tooth-plate was missing. After a fruitless search in the bed and upon the floor he concluded he had swallowed it, and immediately sent for a physician, who, after introducing an œsophageal probang, assured Mr. K—— that he had pushed the foreign body into the stomach. The plate, which was of rubber, had four incisor teeth attached, and measured one and a half inch from front to rear, and one and a fourth inch in width.

Fig. 5.

I was consulted on the third day. He complained of intense pain in the region of the stomach, which was increased at each act of swallowing. The expression of countenance was anxious, his general appearance that of a person after a severe illness.

Passing an olive-pointed probang, an obstruction was found at cardiac end of œsophagus, *thirteen and a half inches from incisor teeth.* Bringing the instrument in contact with the foreign body, a metallic click could be distinctly heard.

The exertion of ordinary force failed to remove the obstruction. Appreciating the liability of injury to the parts, prolonged and greater effort was deemed unwise, and an operation—œsophagotomy—was suggested to the patient. To this he demurred, preferring to wait for at least a few days. Advising him of the danger of delay, I left him. On the fifth day he entered the Troy Hospital. Since last seen says he has suffered intensely; is able to swallow but small quantities of liquid nourishment, which act is attended with increased pain.

Efforts to dislodge were again made without success. He was now ready and anxious for an operation, and the following day was therefore appointed. The operation was done at 11 A.M., with the assistance of Dr. Nichols and members of the hospital staff.

Reaching the œsophagus in the usual manner, from the left side, it was opened vertically upon a lithotomy staff. The foreign body was found to be quite out of reach of the finger. It could be readily felt, however, by introducing a long forceps, but in this manner it could not be grasped securely enough to admit of extraction.

Unsuccessful attempts were then made to pass beyond and over the plate loops of silk. Finally, a sponge attached to the probang was carefully passed beyond the obstruction, and upon removing it the sponge became engaged, and the foreign body was brought to the opening and removed by the fingers of the operator. The wound was not closed.

It should be stated, that in carrying the dissection as near the sternum as possible, the anterior jugular vein was divided. It was soon secured, with but little loss of blood, and without apparent entrance of air. The patient was put to bed, and a nutritious and stimulating enema administered soon after. He rallied well. For the first few hours was allowed to dissolve bits of ice in the mouth. Nine hours after the operation he drank, by holding the edges of the wound together, a goblet of milk. The temperature then—the highest point reached during convalescence—was 100⅘°. The recovery from this time was very rapid. On the ninth day he sat up and ate six oysters, a slice of bread, and one egg. The wound closed on the eleventh day. Three weeks from the day of operation, he left the hospital, cured. The following week he resumed his usual avocation—that of a farmer.

In reviewing the various steps of an operation to reach the œsophagus by external incision, Professor Cheever[1] so well expresses what I want to say that I cannot do better than quote him *verbatim*. A more definite or concise statement has not, to my knowledge, been published. He says: "It appears, first of all, that this incision cannot well exceed three to three and a half inches in length. This is about the distance, in average necks, from the top of the thyroid cartilage to the sternum. If we cut above the thyroid cartilage we endanger the hypoglossal nerve and lingual artery, in a deep dissection; and, more important, the *superior laryngeal nerve*. The latter crosses the space between the hyoid bone and top of the thyroid cartilage to enter the larynx, and its section would destroy the sensibility of one vocal cord, and one-half of the glottis. Through a comparatively short incision, therefore, we are obliged to make a very deep dissection down to the prevertebral muscles, and to draw various important structures out of harm's way as we proceed. First, the carotid sheath, containing the artery, vein, and pneumogastric nerve, which approximate closer and closer toward the œsophagus, as we descend the neck. Above and below are the superior and inferior thyroid arteries; on the inside the thyroid gland; below the finger, the sympathetic nerve. And, finally, running between the œsophagus and trachea, to the back of the larynx, the inferior, or *recurrent laryngeal nerve*, the motor nerve of the larynx, whose section would paralyze one-half of the glottis; and the partial division of some filaments of which, in one case of œsophagotomy, led to a permanent alteration of the voice. This nerve, lying upon the front of the œsophagus principally, is to be avoided by opening the gullet toward its *posterior* part. The œsophagus is easier found also on the *left* side of the neck, as it naturally inclines to that side. And the rule has been laid down that œsophagotomy should be done on the left side as the place of election, unless we are sure of cutting down on the foreign body on the *right* side. The deeper dissections being carried on chiefly with the director, it is possible to reach the œsophagus not only *without injuring any nerves*, except the unimportant superficial branches of the anterior cervical plexus, but also *without tying a vessel*. There is, I believe, but little danger of wounding the *recurrent laryngeal nerve* if, before opening the gullet, a lithotomy staff, or some such curved instrument be introduced by the mouth, and its walls pushed well forward. This facilitates the operation by bringing the parts well into view."

The permanent alteration of voice in Case I. was not due to the operation, for at the time of my first visit, the fourth day, I was informed that he had been unable to *speak above a whisper* since the day after the accident. The injury was probably done while making fruitless attempts to dislodge.

There is a diversity of opinion as to the treatment of the patient after the operation.

Boyer, it is said, was the first to advise absolute diet for a week and the non-employment of elastic tubes to feed the patient through.

Syme advocated the early use of the tubes, and the weight of authority seems to lean in that direction, yet it is doubtful if many have spoken from actual experience. Cheever believes that the irritation of passing tubes, however gently, is considerable; and the risk of touching granulations, thus lessening chances of early repair, is very great. I believe this to be true, for a tube cannot be passed with any degree of accuracy when once it is within the œsophagus, making contact with the wound almost certain. Experience has taught me to believe that the use of tubes is not essential, and that there is nothing to contraindicate the administration of liquid nourishment in small quantities, by the mouth, within a few hours after operation. The danger of infiltration among the long muscles, leading to suppuration, as suggested by Cheever, is, I think, *nil*.

It has occurred to me that the frequent passage of the escaping fluid through the œsophageal wound during the process of repair, has a tendency to *evert* its edges. If this be so, and it seems reasonable, such a condition of things is to be encouraged.

[1] Two Cases of Œsophagotomy, etc. Boston. 1868.

ON THE PREPARATION AND USE OF OXYGEN AND ITS CONGENERS AS REMEDIAL AGENTS.

By SAMUEL S. WALLIAN, A.M., M.D.,

BLOOMINGDALE, N. Y.

Following the appearance of my paper on oxygen, etc., in The Medical Record of October 27 and November 10, 1883, I received from every direction a flood of professional inquiry. To a few applicants I made brief response by letter.

As the tenor of all was the same, viz., an eager anxiety for definite practical details in the matter of preparing and exhibiting the agents in question, and since I found it utterly impracticable to make satisfactory reponse by letter to even a few of the many inquirers, I will, at the urgent request of numerous correspondents, endeavor in this paper to summarize such practical details as may assist those practitioners who have not as yet given much attention to the subject.

Apparatus.—Those practitioners who live in or near large cities may find it more convenient to purchase both oxygen and nitrogen monoxide compressed in iron flasks; suitable contrivances being provided for their proper expansion, dilution, and dispensation. A constant advertiser in The Record offers to supply "pure oxygen" and suitable inhaling apparatus for medical purposes, and the dental depots supply the nitrogen monoxide compressed so as to be readily portable. If one can trust to the manufacturer for the absolute purity of his

product, this method of procuring the gases saves a world of trouble and vexation; but as I have had no personal experience with them I can neither commend nor condemn. The only feasible method for those who live at a distance from these sources of supply, and the least expensive for all, is by procuring the necessary apparatus and manufacturing at one's own office.

For storage I use a meter-holder made of sheet zinc or tinned copper. A convenient size is thirty inches in diameter by about thirty-two or thirty-four inches in height—the width of ordinary sheet zinc will do. This will admit a bell or receiver, corresponding to the gasometer of ordinary city gas works, with a capacity of upward of a hundred gallons. In a large practice, or in hospitals, much larger receptacles may be used, but it is better to have several of moderate size rather than one large one, thus enabling the physician to have various admixtures and dilutions on hand at the same time.

The tank or holder, answering to the well of gas works, is to be filled with pure water, and should have a tap with rubber cork, or a faucet, near the bottom for convenience in drawing off the water when necessary to renew it. To facilitate this operation it is well to place the tank on a frame or platform eight or ten inches high, and it should also have a false bottom of wood beneath the metal one to strengthen it. A broad metal hoop at top, bottom, and middle is necessary to keep it firm in shape. The inverted bell or gasometer should have a gas-cock soldered into the top, through which to admit the gas, with ears at opposite sides by which to suspend or balance it. For the latter purpose cords, weights, pulleys, and a light framework will suggest themselves. An approximate scale, estimated in either cubic inches or centimetres, as preferred, can be readily arranged on this framework, or on the side of the bell itself, for the purpose of measuring the volume of the gases as manufactured, commingled, or respired.

For any considerable practice, not less than three reservoirs will be found necessary, as well as convenient. In one should be kept, at all times, a supply of pure oxygen; in a second, pure nitrogen monoxide; the third may be used for any standard admixture or dilution of the two, or either of them, as desired.

As an external finish a coat or two of paint, or graining and varnishing in imitation of wood, adds to the appearance and durability of the metal reservoirs.

Both the gases used must be well washed and purified as they are evolved. I use a series of four or five wash-bottles for this purpose, connected by means of glass and rubber tubing.[1] These bottles may be procured ready fitted from manufacturers of glassware through your local druggist, or you may fit them yourself at less expense.

For this purpose procure half-gallon or gallon specie jars, with rubber corks to fit, each cork to be perforated with two holes, say three-eighths of an inch in diameter, for the insertion of the glass tubing. Common corks can be made to answer by carefully cementing them with fine plaster-of-Paris after the fittings are all in position.

Select the soft or soda glass tubing of about three-eighths of an inch calibre, and not too heavy. This can be readily broken into any desired length by first nicking it on one side with a sharp file and then bend at right angles, after heating in the flame of a gas-jet or of an ordinary spirit-lamp. Hard varieties of glass may be bent by thrusting the ends into a bed of glowing coals for a few moments, should the flame heat prove insufficient.

A copper retort with suitable connections for the preparation of oxygen can be procured from any dealer in chemical apparatus. The size selected may vary from one to four pints capacity as needed. Common glass retorts may be used in lieu of copper for generating oxygen, but the bills for fractured glass and the results of occasional explosions render them both vexatious and expensive.

For preparing nitrogen monoxide the same apparatus is complete, except that a glass or porcelain flask must be substituted for the copper retort. A half-gallon Florence flask fitted with perforated rubber cork and long bent glass tube of good calibre, to connect with the first (or empty) wash-bottle, makes a very satisfactory arrangement. Platinum or gold flasks are perfect, since they thoroughly resist the action of the chemical used, but are, of course, expensive. I prefer to use glass for various reasons, even if there is, as a result, a fractured flask and a bespattered floor or table occasionally. In glass the material can be more closely watched during the process, and the danger of applying excessive heat more surely avoided. The first or empty wash-bottle acts as a safety valve, preventing reflow of water into the flask in case of sudden withdrawal of heat or of an accident.

Chemicals.—The materials used for preparing pure oxygen by the process now under consideration are potassium chlorate ($KClO_3$) and manganese dioxide (peroxide) (MnO_2).

The latter, it is hardly necessary to state, is not chemically changed during the process, but acts merely by its presence. Both chemicals should be as pure as can be procured, thoroughly dried and finely pulverized previous to using. It is even better to evaporate the water of crystallization in case of the chlorate, and it must be very thoroughly rubbed up with the manganese in a dry mortar, the most favorable proportions being four or five of the potassium to one of manganese. The exact proportion is not essential and need not be uniform, one part of the former in eight or ten of the latter working very well. Since it is so difficult to make it fine enough by hand, and requires so much labor withal, I prefer to buy the pulverized chlorate of potassium of the brand known as "chemically pure."

For nitrogen monoxide, procure simply pure fused crystallized or granulated ammonium nitrate (NH_4NO_3). It will not matter which of the three varieties is selected, so that the salt be pure and clean.

Heat decomposes this salt into nitrogen monoxide (N_2O) and water (H_2O). If the heat be too great or too rapidly applied, fumes of nitrous or hyponitrous acid (HNO) will be driven over, to be absorbed by the water in the wash-bottles.

Chemical manipulations.—To prepare pure oxygen fill the copper retort half full of the prepared potassium and manganese mixture, connect securely with the series of wash-bottles, the last one of the latter to be connected by a long rubber tube to the gas-cock in the bell or meter. Apply heat by means of the sand-bath, a jet of house gas, a spirit-lamp with several small wicks or one large one, or by a small kerosene stove. No gas is given off until the whole mass has been heated to a rather high and uniform degree, at which point the evolution is sudden and rapid, frequently trying the wash-bottles and connections severely. The heat should be promptly diminished at this juncture, to be increased again as the material begins to be exhausted.

The reaction consists simply in the disengagement of both equivalents of oxygen from the potassium chlorate, potassium chloride (KCL) resulting. The flask is to be disconnected from the wash-bottles promptly when gas ceases to pass over.

For nitrogen monoxide fill a Florence flask (those of German glass answering best) half full of ammonium nitrate; connect securely with the dry wash-bottle by a long bent glass tube (thirty inches is not too long), and it is well to wire the cork to the neck with copper or platinum wire to prevent its being forced out at a critical moment.

Apply heat gradually at first, preferably by means of a sand-bath, or very cautiously by means of the same

[1] The following is a fair assortment of tubing for fittings: Four pieces ¼-inch glass tubing, thirty inches long; four pieces ⅜-inch glass tubing, thirty inches long; one piece ⅜-inch rubber tubing, eight feet long; one piece ½-inch rubber tubing, six feet long.

lamp used in the process for oxygen. If the sand-bath be dispensed with it will be a good precaution to suspend the flask over the flame by a wire, and keep it in gentle motion in order to apply the heat more evenly and prevent the liability to fracture.

After a few accidents each novice will learn discretion and acquire the "knack," so as to make as little havoc with fragile apparatus as is possible. With the best of management and the nicest adjustment of all the conditions accidents will sometimes happen, and some taint of foreign elements will pass over into the first two wash-bottles, which will therefore, more frequently than the others, need to be emptied and refilled. More care and watchfulness are required in the preparation of this gas, and the process is slower than that for oxygen.

Suggestions for administration and for determining when and when not indicated, together with approximate dosage and condensed reports of a few additional cases treated, will be given in another paper.

The most difficult part of my task remains, since in no other form of therapeutic effort is more careful discrimination necessary, and in none are we confronted by a greater dearth of precedent. Ordinarily the diagnosis furnishes the indication, and the age, condition, and temperament of the patient are accredited as safe guides to the proper dosage.

The agents now under consideration are potent for good or evil in a superlative sense, and cannot be so exhibited. Nor have we in our libraries half a century's accumulations of literature on the subject, to which, as in ordinary cases, we can refer for aid in case of a dilemma.

One of the first misconceptions, or misapprehensions, to be thoroughly uprooted—for it is always necessary to unlearn errors before we can comprehend facts—is the inference or impression that since these agents are principally used by inhalation they are, on this account, particularly adapted, if not practically limited, to the treatment of pulmonary complaints. Nothing could be farther from the truth, as will appear from the general tenor of arguments used and facts presented throughout this series of papers. Oxygen may be now, or may in time become our chief reliance in combating the strumous and tubercular, as well as other diatheses; but it is not and will not be because it is taken directly into the lungs, the apparent principal seat of tubercular manifestations.

Its specific action is by and through its absorption into the blood and its direct and rapid distribution to every tissue throughout the entire system. It thus becomes, as already set forth with sufficient emphasis, an important source of supply to the blood, *an element of repair and nutrition*, already prepared for direct and immediate assimilation, requiring neither gastric solution nor intestinal modification in order to become an integral part of the vital organism. Its effects, therefore, must not be compared with those which follow a dose of "medicine" in the ordinary acceptation of that term. Hence, while certain immediate or acute morbid conditions are quickly removed by its timely exhibition, it cannot be ranked as a drug to be divided into definite doses and exhibited promiscuously in all acute and chronic diseases at stated intervals, as is the case with the ordinary articles of the Pharmacopœia.

If, therefore, I were to be asked whether the oxygen treatment will "cure" this or that particular malady or disease by name, as phthisis, carcinoma, rheumatism, epilepsy, I should promptly answer, No, it will "cure" no disease whatever. If, on the other hand, a professional brother should inquire, In what diseased conditions do you consider it particularly indicated? I should as promptly respond, *In every chronic morbid condition of which it is possible to form a conception.*

This may seem an extravagant estimate, but it really is not, since the question is like asking in what conditions of the system is it proper to administer nourishment? It is merely recognizing the view now coming to the front in medical philosophy, that, in the language of Ordroneaux, "We are to treat it [disease] not as a personal devil entirely, to be exorcised by philters and mummery, but rather as *the perversion of a natural state struggling to regain its equilibrium.*"[1]

Another stereotyped error in connection with the use of oxygen as a remedy must be eradicated from the average medical mind. It is assumed, on the basis of an ancient chemical dogma, that this element is pre-eminently a *destroyer;* that it is the principal, or even sole office of the oxygen inspired to break down used tissues, to eliminate refuse material, to "burn up" waste products; and that more oxygen means simply and necessarily more extensive waste, more rapid destruction—a hotter fire! This is another of the superannuated myths of science. It is true that living is synonymous with wasting, disintegration—*burning*, if you insist on the misnomer—but to cease to waste, to interrupt disintegration, to *put out the "fire,"* even for a moment, is to cease to live; it is irrevocable death. Nor can reparation, or even primary assimilation, proceed without its twin process—destruction. Admitting all this as abundantly established by both analogy and observation, there is still every corroboratory assurance, in both chemistry and physiology, that the element under consideration is less a *de*structive than a *con*structive agent, less a detergent than an aliment, less a *burner* than a *builder*.

Again, the underlying idea in all rational therapeutic endeavors, aside from surgical conservation of structure and the temporary palliation of excessive pain, is to hasten metamorphosis, both destructive and constructive, since it is universally recognized that destructive action—elimination, depuration—is but one and a very essential part of constructive change. It is the thrusting aside of obstacles which impede or bar the progress of true repair and rebuilding.

On the part of those who have been in the habit of thinking, teaching, and acting in the old rut—for rut it certainly is—it will take some time to fully comprehend, and will require a considerable effort to frankly admit this; for the rut has long been revered as the regular way, and in it we have always had, and still have, plenty of company, and that of eminence the most unquestioned. Nor is it any novelty, or in the slightest degree an innovation, to assert this. Acknowledged authorities in physio-chemistry have all along taught it. It will be a surprise to even well-read and experienced members of the profession to refer freshly, in the face of this assertion, to standard works on physiology and see how strong and positive is the evidence to this effect—evidence which most of us have all along blundered over, ignored, or but half comprehended.

"To describe fully the physiological action of oxygen would involve a description of the processes of respiration, sanguification, nutrition, and tissue-change, for to all these, and to life itself, it is essential."[2]

"Preyer showed that a greater saturation from oxygen inhalation is, *a priori*, probable, . . . and Demarquay proved it by showing that suppurating, indolent, or unhealthy wounds on the extremities of animals became quickly florid and hyperæmic when pure oxygen was inhaled. . . . Allen and Pepys, and later Limousin, showed that by inhaling an equal quantity of atmospheric air at one time and oxygen at another double the amount of carbonic acid was expired, and this increase continued for fifteen minutes after the inhalations had finished."

"Other observers have reported that the elimination of uric acid during a course of oxygen inhalation is markedly lessened, *i.e.*, that more complete combustion occurs within the system (Schmidt's Jahrb., t. i., s. 28, 1865)."[3]

[2] Phillips: Mater. Med. and Therapeutics, vol. i., p. 2, ed. Wood's Library, 1882.

[3] Phillips, op. cit., p. 5.

Kollman found that the quantity of uric acid in an equal amount of urine was reduced nearly fifty per cent. by free oxygen inhalation. In one experiment the amount of acid fell from one hundred and thirty-four to twenty-five milligrammes.

Gubler's experiments proved that active inspiration of pure oxygen gas slowed the pulse and respiratory movements, produced a general sense of comfort, did not cause dyspnœa, and that the pause between inspiration and expiration could be prolonged from the ordinary limit of thirty to as much as ninety or one hundred seconds after breathing oxygen ; and as a result of his observations, he asserts that the blood receives the gas in proportion to its physical capacity for it, rather than in proportion merely to the vital necessity of hæmatosis. The globules absorb what they need, while any excess circulates free and enters into combination only as the hæmoglobin loses oxygen in passing through the capillaries.

Quinquaud, by certain chemical tests, which, to make them reliable, need corroboration, estimated that the capacity of the blood for oxygen in healty subjects was quite uniformly two hundred and forty cubic centimetres of oxygen to every one thousand grammes of hæmoglobin.

The experiments of Buckheim, Klebs, Husemann, Naoumoff, Beliaieff, Savory, Richardson, Ewald, Hering, and others, have not given us much additional light on the subject. They were chiefly of that crude, forced, and unnatural character, too common in physiological experiments, which adds so little to our practical knowledge of the "action" of any remedy when properly exhibited. For example, what would it profit the pathologist to learn, by cruel experiment on the lower animals, or perhaps on some helpless, hospital-stranded human wretch, that an exclusive diet of absolute alcohol produced a train of untoward symptoms and speedy death ? Would we therefore proscribe all the alcoholic mixtures—brandy, gin, wine, whiskey, etc., etc. ?

Nature does not suggest the use of oxygen in a "pure and nascent state," as used by these experimenters, and I do not consider such use of the agent, unmixed and undiluted, permissible, much less advisable, except in a few emergencies, and then only to cover the exigencies of the particular cases as presented. Hence I have little interest in the class of experiments referred to. *Tests of the gas as a therapeutic agent must be based on conditions which do not do violence to well-known and well-proved natural laws.* The safe guides in this, as in all therapeutic investigations, are common-sense, the recognition of known facts, and the simple rules of analogy. Above all, we must "take a hint from nature."

Among the acute or immediate conditions which oxygen and its congeners can be made to promptly, safely, and surely relieve, may be cited *asphyxia*, from drowning, hanging, or from inhaling carbon dioxide or other noxious gases ; *suspended animation*, from syncope and from opium or chloroform narcosis ; *poisoning*, from various toxic agents ; *spasmodic asthma* (the paroxysm); *obstructed respiration*, as in diphtheritis and membranous croup ; and in *cyanosis*, from whatever cause.

Of the many chronic conditions which may be confidently attacked, I may specifically mention *anæmia* (Birch, Demarquay, Da Costa, Dujardin-Beaumetz, *et al.*) ; *chlorosis* (idem) ; the *cachexiæ* and *dyscrasiæ* in general ; all the *indigestions* and dependent disorders (Hill, Beddoes, Birch, Goolden, *et al.*) ; *struma* and *tuberculosis* (omnes cit.) ; *empyæmia ;* chronic *glandular enlargements ; intra-thoracic* and *intra-pelvic abscesses* and *degenerations* ; *epilepsy ; emphysema* (palliative) ; *asthma* (curative) ; the *typhoid state ; zymosis, septicæmia,* and *paludal poisoning ; neurasthenia*, and nearly all forms of *neuralgia*.

From this imperfect generalization, it will not be difficult for the observant medical mind to discern the special indications and contraindications for treatment in any given case.

It may be asserted, in general, on rational as well as experimental grounds, in connection with this treatment, that those chronic cases show most marked and striking results which are selected from the great army of house-prisoners, "delicate" people who, from necessity, habit, preoccupation, or negligence, have been long deprived of wholesome air and everything like active out-door life ; or who have long suffered from miasmatic location, sedentary occupations, or unsanitary surroundings ; or from those who have been too tenderly reared—over-coddled (and this virtually includes every close resident of a populous city). To these may be added the phlegmatic, the "lymph-albuminous," and the lazy—of whom every community shows numerous examples—patients with sluggish circulation, small respiratory apparatus, torpid or enlarged livers, fatty heart or kidneys, and with habitually retarded excretory functions generally.

As far as individual experience with oxygen goes—my first cases were treated sixteen years ago—I have found thoroughly satisfactory, and in some instances very remarkable, results in cases of inveterate asthma. As a palliative of the immediate attack, a mixture of oxygen and nitrogen monoxide has invariably given instant and happy relief ; and the continued use of the two, variously modified, has never failed, in my hands, to effect a, to all appearances, complete and perfect "cure." If more extended trial proves equally successful, the treatment might very properly be termed a "specific" in the treatment of this distressing malady, which so often resists all ordinary as well as extraordinary measures.

In the severer forms of the indigestions the results have been scarcely less brilliant. Scanty or suppressed secretions are gradually restored, absorption and assimilation resume normal activity, and the functions of depuration and defecation, long deranged, obstructed, or interrupted, are surely, normally, and in a medical sense permanently restored.

Hill's first experiments with oxygen (1820) covered cases of hydrocephalus, epilepsy, chronic arthritis (gouty ?), paralysis, and morbus coxarius. In each of these he reported flatteringly encouraging results.

Another, by no means unimportant, but as yet almost wholly ignored use for oxygen, is in connection with the administration of anæsthetics. On purely rational grounds, as well as from some years of practical experimentation, I am thoroughly convinced that the dangers heretofore presumed to be inseparable from the use of ether, chloroform, and other anæsthetics can be reduced to a minimum, if not rendered altogether nil, by the timely, previous, and perhaps occasionally subsequent exhibition of oxygen. A few inspirations of the gas, slightly diluted, taken just before inhaling chloroform or other anæsthetic, while it does not interfere with the degree of anæsthesia produced, effectually prevents the usual untoward symptoms—nausea, headache, delirium, etc. And while not materially abbreviating the stage of complete anæsthesia, it shortens the recovery stage and effectually forestalls the symptoms of imminent danger which so frequently alarm the operator and jeopardize the life of the patient.

In the use of nitrogen monoxide as an anæsthetic in short surgical operations, dentistry, etc., the effects are much more desirable when a certain percentage of pure oxygen is added.

On this point I would quote a summary of results arrived at by Dr. Klikowitsch after a series of experiments in Prof. Botkin's laboratory, at St. Petersburg (*Virchow's Archiv*) :

1. Anæsthesia induced by it [nitrogen monoxide] is closely associated with insufficient oxidation of the blood, and hence not absolutely free from danger.

2. The association with it of twenty per cent. of pure oxygen completely removes all possibility of asphyxia, without interfering with the completeness of the anæsthesia.

3. By the use of this mixture the heart-pulsations of healthy subjects are increased, the pulse-wave diminished, respiration increased in depth but decreased in frequency; these effects lasting from three to five minutes.

4. In four cases of weak heart-action, the exhibition of this mixture produced no unfavorable symptoms. On the other hand, the pulse increased in strength and decreased in frequency; these effects lasting from one to two hours.

5. In cases of disturbed respiratory innervation, the mixture rapidly removed the symptoms of deficient blood-oxidation and regulated the respiratory rhythm.

6. This mixture quickly relieves suffering in angina pectoris, and when pushed, produces very perfect transient anæsthesia.

7. It is preferable to chloroform as an anæsthetic in labor.

8. Vomiting and cough of reflex origin are arrested by a few inhalations of these mixed gases.

(To be continued.)

A PLEA FOR THE ARTIFICIAL FEEDING OF INFANTS WITH COWS' MILK.[1]

By JOHN BINNIE, M.D.,

POYNETTE, WIS.

I ADMIT that nothing is equal to a healthy mother's breast; I as truly believe that many a mother's milk is not so good as proper artificial feeding, and I would recommend artificial feeding more frequently did I not know the great liability to carelessness on the part of the nurse in causing sickness, and even the death of the child. My experience has been quite extensive, but entirely with cows' milk, except in two cases, where we added an infant food. I can say nothing of the various prepared foods and milks sold by the trade. As I live in a healthy agricultural district of Wisconsin, among mixed nationalities, I advise the selection of a good healthy cow, between the age of four and ten years, of mild disposition, which has been giving milk from four to eight weeks previous to the birth of the child.

The selection made, she should be cared for as follows, viz.: fed on good clean grain, and hay free from *must*. Roots, if any are fed, should be of good quality, and she should have plenty of good clean water from a living spring or well. Her pasture should be Timothy grass or native grass, free from weeds; clover alone is bad. When mixed with other grasses it will do. She should be cleaned and cared for like a carriage-horse and milked twice a day. In a few instances, during the very hot weather, I have recommended milking three times a day. The milking is always to be done at the same time and by the same person. This is very important, as those having experience with cows will readily understand. The milk should be kept in a cool place, away from vegetables of all kinds, or any odors, as milk is exceedingly sensitive to all such agents. You must caution the nurse to be especially careful during thunder-storms, as milk will sour then do what you will.

Further, I believe some cows are unfit by nature for feeding infants. In feeding the infant everything connected with the utensils must be kept scrupulously clean. Take three or four parts of warm water to one part of milk, and a little fine white sugar; bring all to the temperature of the body. Give the child about two ounces every two or three hours. This strength is generally sufficient for the first two or three months, when you will gradually increase the proportion of milk, so that by the time the child reaches four months it will be taking milk and water about equal parts, and an increased quantity. These are general remarks, and may require changing to suit individual cases. No absolute rule can be laid down that will be suitable to all cases. The condition of the child must be the guide. Should the child appear to be insufficiently nourished, increase the quantity of milk to water, or use barley-water in place of simple water, especially so if any tendency to diarrhœa is present. I have seen cases of diarrhœa from too much water yield at once to an increase in the proportion of milk and the substitution of barley-water. You will also get diarrhœa from too great a proportion of milk, or if the quantity taken be too great; the physician must be on his guard to determine which cause is operating in the individual case. When the food is too rich, the diarrhœa generally follows immediately upon some change that has been made in its food, or the child may become fleshy at first. And this misleads both the nurse and physician; they reason that the child has been doing better since the last change in its food. In these cases we often see preceding, or simultaneous with, the onset of diarrhœa a crop of red raised spots on the face or extremities, or both, of the child. This, with the fact that it had increased rapidly in adipose tissue for a time, should call our attention to its food as being too rich or too great in quantity. It may call for an examination of the condition of the cow or her pasture. I believe pure clover very liable to produce this eruptive condition of the child.

The dangers from overfeeding, whether by too large a proportion of milk, or too great a quantity given, are greater than the opposite conditions, especially so during hot weather. The cases are rare where the child can take pure milk with safety before the ninth month, and according to my experience not before the year.

I think well of barley-water during the heat of summer and at any time when a tendency to diarrhœa exists, and I doubt not it might be of service in the opposite condition.

An infant food, added to the milk as before prepared, did well in my two cases. As before stated, the condition of the child is the best guide. When doing well, let it alone and make as few changes as possible. Increase very gradually the strength of its food.

I do not allow any solid food until after a number of teeth are through. No table-feeding of any kind. I have seen children fed as above never sick a day, and as healthy as any I ever saw nurse a mother. I have seen the opposite from a violation of the rules continue until the nurse became more careful. Such carelessness on the part of a nurse ought not to condemn artificial feeding. I am fully persuaded that a child can be raised with as much certainty of living as when nursing the mother, if the necessary care is taken. The causes of failure, as I have found them, are:

1. Want of cleanliness of the utensils.

2. Carelessness in the preparation of the food, as to the exact proportion of milk and water, at each meal.

3. The want of regularity as to time and quantity of feeding.

4. Changing from one cow's milk to another, or using mixed milks of different cows.

5. Allowing the child to nurse or drink too rapidly. The slower the food can be taken without tiring the child the better. Making any of the above mistakes may produce derangement, while some children are permitted to violate them all and live, thus proving the exception to the rule.

I have not written this either to recommend or condemn any artificial foods, or in any way to detract from the value of them; but I have thought there was a tendency among some of the profession to make the artificial feeding of infants altogether too artificial, and to try and supplant milk entirely, or give it, to say the least, a secondary place. This cannot be done successfully. We had better devote more time and money to getting pure fresh milk; then, if thought best, add your artificial foods.

[1] Read before the Columbia County Medical Society, July 31, 1884, held in Portage.

A CASE OF TRAUMATIC TETANUS CURED BY THE INTERNAL AND LOCAL USE OF SULPHATE OF MORPHINE.

By J. W. STICKLER, M.S., M.D.
ORANGE, N. J.

On June 4, 1884, I was called to see T—— J——, aged eight years. In attempting to cut some hay in one of the old-fashioned hay-cutters, he brought the knife down upon his left middle finger, about midway between the tip and the first joint. As the cut seemed to extend about half through the finger I thought it would be wise to endeavor to save the part by carefully coapting the cut surfaces. To do this I inserted a few fine sutures. The wound, however, did not unite, suppuration causing the surfaces to separate. As it was manifestly useless to again attempt to save the end of the finger, I determined to amputate at the first joint. In this operation I was assisted by Dr. J. Y. Simpson. The flaps united quickly, and the boy did very well till June 18th, when he developed tetanoid symptoms. He had pain along the anterior attachment of the diaphragm and in his back, difficulty in swallowing, and spasmodic contractions of the muscles about his mouth. His lower extremities were at once placed in a hot mustard bath, hot poultices applied to his abdomen, and a mustard plaster to the back of his neck. He was then given, per orem, ℥x. of Magendie's solution of morphine, and wrapped in a blanket. The following day there were frequent contractions of the muscles of the face, throat, and trunk; pain in the epigastric region was quite distressing; swallowing of solid food was difficult, even water excited a mild spasm of the throat muscles. At this stage of the disease I asked Dr. Wm. Pierson to see the case, in consultation. He suggested the application to the part of poultices containing morphine (gr. j. each). He was also given twice daily (9 A.M. and 4 P.M.) twenty-five to thirty-five drops of Magendie's solution of morphine, per orem, the dose varying within the limits named, to suit the emergency of the case. Large flaxseed poultices were constantly applied to his back and abdomen, and he was carefully shielded from draughts. After beginning this treatment there was sufficient opisthotonus to make it possible to pass the hand and forearm between the bed and the patient's back. This condition lasted about seventy-two hours. The mouth at that time could not be opened wide enough to admit the index finger. His food consisted of milk and broths. Constipation was a troublesome complication, requiring the occasional use of croton-oil in one-drop doses.

By degrees the rigidity of the various muscles disappeared, the patient being restored by July 1st to a normal condition, so far as the use of the various parts of his body was concerned.

Malarial Gastralgia.—Dr. N. O. D. Parks, of Ashton, R. I., writes: "The following case may prove interesting as an example of the hydra-headed manner in which malaria manifests itself. K. H——, a young married woman, has been subject to severe attacks of gastralgia since the birth of her first child about ten months ago, when they occurred for the first time, and have been hitherto amenable to treatment. She had one on June 7th, and called in a physican who administered morphine hypodermically. I was sent for June 10th. She seemed to derive no benefit from morphia, viburnum, Hoffmann's anodyne, nor any of the usual remedies, external or internal, the paroxysms apparently subsiding of themselves after the lapse of four or five hours, to return with increased violence, at first every other day, but finally they recurred every morning, accompanied by vomiting, which brought no relief. This periodicity led me to administer quinine in full doses, which promptly aborted the attacks. After three days I lessened the amount of quinine, and prescribed arsenic in small doses, and she has had no recurrence of the malady."

ON MURIATE OF LIME.

By JOHN C. PETERS, M.D.,
NEW YORK.

Some time ago The Medical Record had a very suggestive article on the "Uses of the Muriate of Lime." I have found additional material in the works of the late Dr. I. Warburton Begbie. In small and repeated doses it produces increased secretion of mucus, urine, and perspiration; in large doses it is irritant. Fourcroy and many physicians of his time (1775–1809), had much confidence in it against scrofula, but especially the celebrated Dr. Beddoes, who gave it to nearly one hundred patients, in doses of ten drops of the saturated solution to young children, up to two drachms to adults, three or four times a day. He says there are few of the common forms of scrofula in which he has not had successful experience with it. He gives the case of a boy, aged seven years, with a voracious, almost insatiable appetite, protuberant belly, diarrhœa, emaciation, hectic fever, and night sweats, who recovered in two months after taking ten-drop doses, gradually increased to forty; which he took with pleasure in small beer or coffee. The purging stopped first, and then the hectic fever. Also the case of a young lady, aged thirteen, with the same symptoms, and in addition, swelled feet, cough, and difficult respiration. In three days, after taking twenty-drop doses, increased to sixty, the purging stopped; in nine days the feet ceased to swell, while the hectic symptoms and cough disappeared in three weeks, followed by recovery with great gain in flesh in six weeks. Dr. Begbie says he has often cured similar cases, especially the chronic diarrhœa of young children when associated with hectic fever and tumid belly.

Dr. James Wood says he would feel in some degree accountable for the sufferings of all thus diseased if he did not make its virtues known. He used it largely in incipient phthisis, in all the forms of scrofula, and in hectic fever from, or with great discharges. Dr. Ingraham found it to possess great powers in discussing tumors and obstructions of various kinds. The opinions of Dr. James Sanders have already been given in The Record.

Dr. James Hamilton, professor of midwifery in Edinburgh, speaks of it in high terms in scrofula, and Dr. Anthony Todd Thompson asserts that he has seen more benefit from its continued use than from any other medicine. Dr. John Thomson refers to the three muriates, those of soda, baryta, and lime, in scrofula, but seemed to prefer cod-liver oil and iodine.

Begbie has used it most successfully in struma, marked by enlargement of the glands of the neck, after iodine, iodide of potash, and iron and cod-liver oil had failed; and says it is in his power to assert that many instances of very great enlargement of the cervical glands have yielded to its use; also in glandular swellings of the axillæ and inguinal regions, and of the deep-seated lymphatics of the pelvis. It often requires to be taken for a considerable time, for weeks or even months, before its beneficial effects are visibly produced, Usually, however, in the course of a few weeks there occurs a certain degree of softening in the glandular tumors, and the component glands of the mass are more easily distinguishable. With the gradual subsidence of the enlargement there is a notable improvement in the patient as to appearance, appetite, and digestion. If the remedy is stopped too soon, relapses may occur. He has often given the medicine with the greatest regularity for one or two years. He thinks it is best taken in milk, but some prefer water. It has a mawkish, disagreeable taste, which is partly or wholly concealed by milk, but many gradually acquire a liking for it and have a great disinclination to stop it.

Dr. Begbie gives the case of a young woman, with a really frightful disfigurement of the neck, who was decidedly improved in three months, and was in a very satisfactory state in a month more. He refers to two

others. In many cases the disorder will return slightly after the muriate of lime is stopped, but invariably yields again to the remedy, and then the cure is permanent.

In tabes mesenterica, with protracted diarrhœa and exhausting perspirations, the medicine is equally useful, causing a subsidence of the hectic fever, an improvement of appetite, a gaining of flesh and strength, and a gradual restoration to health. In grave disorders of the bowels it arrests diarrhœa, promotes digestion, and favors nutrition. Also in a class of cases marked by depraved appetite, loss of flesh, pallor, protuberant belly, wasted limbs, and more or less febrile excitement of an intermittent or remittent hectic type, with two distinct paroxysms of fever every day. It checks purging, lessens the fever, allays the inordinate appetite, and ultimately restores the patient to health. The red appearance of the tip and edges of the tongue fades away, and the nausea ceases. It acts quicker than lime-water.

It has proved useful in lupus exedens and non-exedens, in local psoriasis, in some instances of ozæna, and in chronic tonsilitis. The recognized dose is ten to twenty grains. The Edinburgh solution has ten grains in every fifteen drops, which is the average dose for a young adult, to be given three times a day in milk. Gradually the doses may be increased to thirty or forty drops. It lessens the acidity of the urine remarkably. All these good effects Dr. Begbie has noticed again and again.

ACUTE IMPULSIVE INEBRIETY.

By T. D. CROTHERS, M.D.,

HARTFORD, CONN.

This term describes a class of cases who suddenly use alcohol to great excess, either for a definite period, or constantly until death or dementia terminates their conscious existence. In many cases they are closely allied to acute mania, and merge into it, but although of the same family group, there are distinct differences. Clinically two classes are prominent, and both begin the same way, but after a time they diverge widely. In one the use of alcohol is continuous, and only varied by the difficulty of procuring it, and the change to opium or other narcotics. In the other a distinct free interval of sobriety follows, usually of definite length, which becomes shorter as the disease progresses. The latter is of a dipsomaniac type, with epileptic tendencies, and may at last become what has been erroneously termed alcoholic epilepsy. Criminality and many strange psychical manifestations appear in this class. The first class of continuous drinkers are marked by the early and profound failure of all the higher brain qualities, dropping quickly from positions of character and reputation to that of moral imbecility, and apparent unconscious realization of duty and obligation to others. My object is to trace some of the apparent causes and symptoms of the early premonitory stage of this affection. These cases have no particular stage of moderately drinking, or period in which wine, beer, bitters, or other of the milder alcoholic drinks are used. They begin at once with poisonous excessive doses of alcohol. Despite all theories it is an unmistakable fact that this condition is an explosion, or the bursting into activity of a long train of causes unnoticed before. It is a sign of brain exhaustion, of diseased conditions that have suddenly concentrated into a craving for the narcotic effects of alcohol. This uncontrollable desire for alcohol or other narcotics is a symptom of profound disease and degeneration, which may be regarded from two points of view, namely, as a congenital or acquired condition.

In the first, or inherited group, I find such cases as the following: A man of good health, temperate, and of reputation, who has insane or inebriate ancestors, but who has lived an exemplary temperate life, drinks suddenly to great excess and never recovers. It may follow some business losses or social disasters, and in many cases it comes on without the slightest reason that is apparent, like a lightning-flash in the clear sky. Another case would be of some hard-working, business, or professional man, who has given signs of nerve and brain failure for years, then all unexpectedly lapses into profound inebriety. An epileptic neurosis or consumptive and hysteric diathesis is found to be present.

In other cases signs of brain defects from heredity are present. Thus a passionate, unreasoning, impulsive brain power; or a brain on the borders of delusions and hallucinations; or a changeable, uncertain brain force, exhibiting many hints of defect will suddenly develop into inebriety. Some writers assert that in such cases inebriety is merely an outlet for insanity, or insanity in another form, which would appear with certainty in the natural progress of the case. This would be expected if a state of moderate drinking was present, but in such cases absolute abstinence from all use of spirits exists up to the moment of the outbreak. In some cases these apparent inherited nerve defects are obscure and unnoticeable, except from an intimate acquaintance, and the outburst of inebriety cannot be traced to any present exciting cause; the only fact of significance is that they had an insane or inebriate and neurotic ancestry. A vast realm of clinical and psychological facts stretch out from this point entirely unknown.

Another group of cases who have a decided neurotic ancestry, and themselves exhibit marks of it in their actions and thoughts, become impulsive inebriates from distinct causes that are traceable. Thus a temperate man of this class will suffer some great loss of property, or of relatives by death; will meet some unexpected disaster, which will profoundly impress and change all his functional activities. After a short incubating period he will begin to use spirits to great excess, either in secret or openly. A prominent governor of a great State, temperate and robust in mind and character, whose father was a hard-drinking man, was suddenly overwhelmed with sorrow at a social wreck in his family. Three days after he went to his stable with a case of brandy, and drank to excess for four days, concealed by his hostler. From this time he has continued to drink at intervals, without control of himself or without conscious reason, and is now a confirmed inebriate invalid.

In another case of a man of prominence, with an inebriate ancestry, sudden bankruptcy through the dishonesty of partners precipitated him into impulsive and profound inebriety, ending fatally in a few months from acute pneumonia. In these cases prominent exciting causes, particularly great strains and profound emotional changes, have fanned into activity a latent neurosis, which otherwise might have remained dormant.

The same results are seen in cases who suffer from some acute disease that is profound and prolonged, such as typhoid fever, malaria, pneumonia, pleurisy, gastritis, and many other diseases which positively affect the integrity of the organism, leaving an entailment or condition of debility from which recovery is very slow. In such cases, particularly where inebriate heredity is present, impulsive inebriety may spring up and go on rapidly to death. A favoring soil is present, and some unknown germ cause has developed it. An almost endless variety of conditions, involving every form of strain and drain, of functional and organic activities, starting from a defective brain and nerve soil merge into this malady. In the acquired form or group the same conditions are seen without the apparent heredity. It would seem that all the conditions have grown up from neglect and the surroundings. A common illustration is seen in the constantly increasing army of business men who steadily overwork, and neglect to obey the simplest laws of health, thus becoming more and more unfitted for the trials and duties of life. Suddenly, after some great loss and strain, they become inebriates and drink without any intelligent reason why they do so. The class who have used alcohol in moderation for a long time, and suddenly

become pronounced inebriates, are very common in all large cities. But the brain-workers, who are intemperate in almost everything except the use of alcohol (in this they are total abstainers), are furnishing an increasing proportion of cases of this form of inebriety. A man who occupies a position as a worker and producer, who is a power in his circle, suddenly poisons himself with alcohol, and keeps it up day after day until death brings relief.

If the causes are not traced to heredity, they will be found in some condition of bad living, overwork, want of rest, and imperfect nutrition. Psychical traumatism is apparent in a certain number of these cases. As an illustration, lately prominent in a distant city. A clergyman, a total abstainer, a man of unusual force of character and health, saw his daughter dashed down an embankment and killed. The next day after he drank to intoxication, and is to-day a periodical inebriate of the worst type. In another case a man of repute was intoxicated at the funeral of his wife and never recovered. In a case under my care a temperate man began to drink to great excess on the sudden return of his son, who was supposed to have been killed on the battle-field. In other instances the mental shock from sudden poverty or unexpected wealth have resulted in this form of inebriety.

Undoubtedly some profound change and alteration takes place in the central nerve system, followed by psychical pain and exhaustion, for which nothing but alcohol brings relief. In these cases a substratum of inherited degeneration may favor this state, or condition of impairment from disease or other cause, which intensifies the inebriety, making it more incurable.

Many of these cases of acute impulsive inebriety are concealed with most extraordinary judgment on the part of the victim. He has become a periodical inebriate, and from symptoms he anticipates the approach of the paroxysm, and conceals himself from observation until the drink storm has passed. Such cases leave work suddenly, and very strangely disappear from the circles of their acquaintances, and a few days or weeks later return, paler and somewhat worn, and resume work as before. This concealment may go on for years, or until death comes from some acute disease. Frequently sexual perversions are associated with this disorder; then the victim will be found in disreputable houses far away from home. Usually this class seek quiet hotels in the interior, or private asylums under assumed names. Others appear boldly in public places and at home, and seem to have lost all pride of appearance, and when efforts are made to restrain them from the drink used, resort to any substitute, and usually find some form of opium or preparation of chloral equally satisfactory.

In a certain number this form of inebriety is followed by paralysis in a year or more, showing that it was but an early state of other disease. In other cases dementia appears, and the drink craving subsides. In others opium and chloral inebriety come on, from which recovery is rare. The prognosis is unfavorable. The craving for alcohol may die out, but other diseases will follow. In many cases acute tuberculosis follows, and in all instances general failure of all the functions point to the gravity of this affection.

Prompt, early recognition of disease and diseased conditions are demanded in all these cases. Questions of vice, will-power, and morals are absurd; medical means and remedies are wanted; for no matter what the case may be in other respects, it is a distinct neurosis that requires positive practical methods of treatment.

The quarantine of an asylum or hospital is needed, where every condition of surroundings can be under control, and where every source of irritation that is removable can be reached.

The work of restoration involves long time and every appliance of science and art which can be brought to build up and strengthen the brain and nerves. If the case has merged into a periodical condition, the paroxysms must be anticipated in the treatment, and all means used to abort and lessen their intensity.

In some instances these periods return with great exactness, which can be anticipated within a day or hour. Then the value of hospital treatment and medical aids are indispensable. Many instances are on record of persons able to realize the approach of these paroxysms, and who place themselves under control or in favorable conditions to pass them with the least injury. One such instance is that of a temperance lecturer who became an inebriate from the loss of his property, followed by acute meningitis and inebriety. He lectures on temperance during the free interval between the drink paroxysms. These return at intervals of ninety days, rarely ever exceeding this time more than a day. After a time he is conscious of the approach of these paroxysms, in certain nervous symptoms, and goes to jail and is locked up in a cell for a week, being fed on beef-tea and milk. Later, he went to a hospital; then, as the paroxysms grew less he could be restrained in a private house or hotel with the door locked and his clothes removed. Now, five years later, the paroxysm still returns, with the same regularity as to time, and he goes to some retired place where he can be locked in; has his clothes taken away, and drinks large quantities of milk, and uses a bromide prescription of about two hundred grains a day for two days or more. After a week he fully recovers and resumes work again for ninety days more. Here the quarantine of a hospital is absolutely essential; nothing but restraint will enable him to pass this critical point.

The continuous inebriate of this class needs not only restraint, but change of surroundings both mental and physical. He is exhausted, and must be built up; his mind must be turned to other channels, and all the surroundings must be stimulating—brain rest, muscle rest, nerve rest, freedom from all strains and drains—these are the corner-stones of treatment.

These cases are not dipsomaniacs; for in nearly all instances there is no delusion or hallucinations; the desire for alcohol is the craving for relief; for a condition of psychical pain or agony that is most positively checked by alcohol. If this drug is not obtainable, other compounds are used. If opium in any form had been at hand, and its first effects pleasant at the beginning, it would be used in preference to alcohol. It is not alcoholism, for the use of this drug is only a symptom of other and more serious trouble. The desire for alcohol is fully satisfied when certain effects are obtained.

These cases are unrecognized except in the most vague, general way. Then simply as drunkards who have occupied better positions, and are now noted for what is termed depravity and great changes of character and purposes of life. Physicians who are called to treat some extreme stage of these cases recognize a realm of psychological mystery which they are unable to solve. Thus the case goes on down to death, unknown and unrecognized, and of course nearly all the means and remedies that are used intensifying the very conditions they seek to lessen.

In a summary of what is known, the following may be stated as a grouping of outline facts:

First.—Acute impulsive inebriety appears in persons previously temperate, who have not used alcohol before. It is marked by profound precipitation and rapid degeneration both mentally and physically.

Second.—All cases can be traced to congenital and acquired conditions, both of which are combined in some cases. Certain causes are found to be peculiarly exciting, and this form of inebriety follows with great certainty. All cases merge into periodical or continuous drinking.

Third.—In the treatment means of prevention and means to conduct the case to a successful termination in recovery should be sought. Quarantine hospitals are

essential, together with all other means which science and art can suggest.

Fourth.—These cases should receive thorough medical study, and all means for relief should be based on such study and its conclusions.

Progress of Medical Science.

Wholesale Poisoning by Illuminating Gas.—An account is given by Dr. G. E. Bentzen, in the *Nordiskt Medicinskt Arkiv*, vol. xvi., No. 1, 1884, of the poisoning of all the inmates of a house by illuminating gas. The house was three stories in height and contained sixteen rooms, occupied by six families, but there was no gas supply and not a single gas-pipe in the house. There had been a break in the gas-main in the street, and from this the gas passed through several feet of earth into the cellar, and was thence diffused through the whole house in such quantity that every inmate suffered in nearly equal degree. The author cites the circumstance as showing how readily the emanations from the soil may pass up into the different sleeping apartments on the several floors of a dwelling.

Embolic Infarction of Muscles.—That the muscles, like other organs, are liable to be the seat of embolic infarctions is a subject which is discussed by M. Girandeau in a recent article, and he thinks that the rarity of this event is attributable partly to the fact that the muscles are seldom examined post mortem, and partly (probably mainly) to the readiness with which collateral circulation is established in cases of blockage of a muscular artery. It is different in the case of pyæmia, where muscular metastatic abscesses are frequent; but in ordinary cases of cardiac disease, where the viscera show ample evidence of embolism, there are very few records of muscular infarction. Cornil and Ranvier, admitting this rarity, state that they have met with two instances, and that they were characterized by absence of hemorrhage. Girandeau supplies notes of three cases. The first was a case of chronic mitral disease with general atheroma. The right sartorius muscle was found to be ruptured, the broken ends embedded in hemorrhagic effusion, and their muscular fibres granular. The spleen contained two old infarctions. The second case of long standing mitral and aortic disease, with arterial atheroma, exhibited a firm, yellow-colored mass in the substance of the pectoralis major muscle, sharply marked off from the healthy tissue, and resembling a visceral infarct. The spleen, kidneys, and brain were also the seat of embolism. A third case, quoted from Lefevre's thesis (1867), was of the same class, and was further complicated with dry gangrene of the left foot and leg. In this case a yellowish gray mass of degenerated muscular tissue occurred in the substance of the vastus externus muscle. These three cases were, it will be seen, of chronic heart disease, and Girandeau asks whether these muscular infarctions could not also occur in the course of acute endocarditis in young subjects. *A priori*, such an event is not impossible; but some experiments made by him at Alfort were wholly negative in their result. He concludes that many conditions may be necessary to the production of the event, among which he enumerates degeneration, roughening, and inelasticity of the arteries; an enfeebled heart; and a more or less marked asphyxial condition, impairing the nutrition of the muscle.—*London Lancet.*

The Genesis of Melanæmia.—Professor Marchiafava and Dr. A. Celli have recently published a most important paper (*Memorie della R. Accademia dei Lincei*) on this subject, giving the results of experiments and researches made in the laboratory of pathological anatomy in Rome—the title of their paper being, "The Alterations of the Red Blood-globules in Malarial Infection, and the Genesis of Melanæmia." It will be interesting, therefore, to learn what were the alterations found The method used for examining the blood was as follows: The blood was taken from a small prick in the finger of the fever patient in different stages of the fever, the finger being previously washed with alcohol. On the drop of blood thus obtained a cover-glass was lightly pressed; it was then pressed against another glass, and the two slipped over each other so as to get a thin film of blood; the glasses were then passed through the flame of a spirit-lamp, so as to dry them. On this preparation one or two drops of an aqueous or alcoholic solution of methylene-blue, recently filtered, was dropped; it was then washed and mounted. By this method the normal red globules were slightly colored blue, unless the coloring matter had been washed out too soon. The protoplasm of the white globules was colored a pale blue, while the nucleus took a deep color. In an individual affected with malaria, however, there were found, in the midst of the normal red discs, other red globules whose protoplasm was altered, this being very evident in those discs which were not colored. These alterations consisted in the presence in the globules of small corpuscles, varying in number, different in size and form, which were colored blue with more or less intensity, but always so much as that they could be distinguished from the protoplasm of the red disc, whether colored or not. These corpuscles, passing from the smallest to the largest forms, are seen as: 1. Granules, generally rounded, which are usually colored a more or less intense blue, and somewhat resemble micrococci; one or more are found in a globule, and sometimes one-third of the red disc will contain one, two, or more corpuscles. 2. As corpuscles larger than those just described, with the appearance of rings in the middle, which may occupy a third or one-half of the red disc. 3. As corpuscles much larger than the first, uniformly colored, or with spaces of spherical, ovoid, fusiform or triangular, which generally contain granules of black pigment in the centre. The larger masses invade, in some red discs, all the protoplasm colored by the hæmoglobin, of which only a very small portion may remain. With these red discs, thus altered, are found bodies colored as the masses above described, and containing pigmentary granules. These bodies evidently represent the last stage of alteration of the red disc, which is thus converted into a body deprived of hæmoglobin, containing pigment. These alterations of the red discs may be followed in all their stages until the conversion of them into pigmented masses. When the red disc contains one or more pigmented corpuscles and a certain portion of its colored protoplasm remains, its normal elasticity seems to be preserved; but when converted into a yellow pigmented body, its elasticity may, or may not be retained, and the disc will adhere to the cover-glass without pressure. Such is a general *résumé* of the microscopic appearances of the blood in malarial subjects, especially during the febrile movement. Are these alterations always found in malarial infection? In some cases the altered red discs are few, in others very numerous; in others still they cannot be found at all. But this is true not only in cases of simple intermittent, but in aggravated cases of malarial infection, and even in the forms of comatose pernicious fever. When these alterations are found the patient always has a peculiar yellowish earthy appearance, the feebleness is very great, and convalescence is more slow, and restitution to health more difficult. Important information might be gained by studying the relations between the degree of alteration of the blood and the clinical course of the malarial disease. The examination of the fresh blood from a case of algid pernicious fever showed the presence of pigmentation in numerous white globules; the red discs were not altered. After coloring by the method indicated, however, the corpuscles were found in the red discs. Microscopic examination of the organs and blood after death showed the described alterations; the same was true of

two other characteristic cases of malarial infection terminating in death. From this it seems demonstrated that in malarial infection an alteration of the red discs takes place, running through various stages, and which commences with the presence of granules and corpuscles, generally spherical, which are colored by aniline. This process is continued by the growth of the corpuscles, by their fusion and the formation of dark pigment in the form of granules and masses, and terminates with the reduction of the red discs into a yellowish pigmented body which is entirely broken up, while the pigment is freed and is deposited in the various organs. But what is the nature of this alteration of the red globules? Without doubt it should be regarded as one of a regressive nature, or better, we may accept Tommasi Crudeli's view, that it is a necrobiosis of the red disc, which is now no longer a red globule, but a circulating body incapable of performing its normal functions. This being admitted, it may be asserted, as regards the seat of the formation and the genesis of the pigment of melanæmia: 1. That the pigment is formed in the blood-vessels, and in the circulating blood; and, 2, that its origin is the coloring matter of the red disc, and that it is formed in the protoplasm of this disc. The first conclusion is evident if it is admitted that the pigment is formed in the circulating red discs, and it is in accordance with what has already been shown by Kelsch and Arstein. The second conclusion is not less evident, since the dark pigment is deposited as the red discs are decolorized, and all the stages of this loss of color and pigmentation may be successively followed. It should also be stated that in certain cases, in which there is so great a destruction of the red discs, there are also found nucleated red discs, macrocytes, and discs differently colored from those ordinarily found. It is well known that nucleated red discs are not found in the normal extra-uterine circulation, except during the first few days after birth; but they are very frequently found in essential and symptomatic anæmia. But hitherto they have not been described in the acute stages of infection. Their presence in acute malarial infection, as well as in the periods of convalescence, is doubtless directly related to the direct destruction of the red discs, and is a sure indication that the functions of the hæmatopoietic organs are so stimulated by the destruction of the discs that they are manufactured more rapidly than is necessary, and are thrown out into the circulation before they have lost their nuclei. These experiments, though not yet complete, certainly explain the alterations of the red disc caused by malaria, and go far toward clearing up the genesis of melanæmia. And although the absence of these alterations in the red globules does not exclude malarial infection, their presence proves it conclusively, as they have been found in no other disease.

Treatment of Laryngismus Stridulus.—In a clinical lecture on this complication of rickets, Professor Widerhofer (*Allgemeine Wiener Medicinische Zeitung*, July 29, 1884) recommends traction of the tongue during the attack, to prevent closure of the glottis, or sprinkling cold water in the face. In the intervals he gives bromide of potassium, and regards this as almost a specific for these spasmodic attacks. The remedy must be given in rather large doses, four grains morning and evening, gradually increased to eight grains. In one or two days, he claims, the attacks will have wholly ceased to occur.

Death from Injection of Iodine in Spina Bifida.—Dr. Woltering relates the following case in the *Allgemeine Medicinische Central-Zeitung*, August 13, 1884. He first operated upon the child when she was four days old, simply puncturing the sac and making pressure with adhesive plaster and a piece of lead. All went well for four months, but the parents were careless about keeping the compress properly adjusted and the tumor reappeared. It was then determined to use iodine. The sac was punctured and about two tablespoonfuls of clear spinal fluid evacuated. One tablespoonful of a solution containing seven grains of iodine and twenty grains of iodide of potassium to the ounce of water was then injected. As the sac was filling, it was noticed that the child stopped breathing. The solution was immediately pressed out again, and every effort made to resuscitate the child. The heart continued to beat for some time, but, in spite of artificial respiration maintained for half an hour, death could not be averted. This case well illustrates the danger of this procedure, immediate paralysis of the respiratory centres having followed an injection of only about three grains of pure iodine.

Tuberculosis of the Tonsils.—It was formerly supposed that tuberculosis of the tonsils never or at most very rarely occurred. In order to determine the correctness of this supposition, Dr. F. Strassmann (*Centralblatt für Chirurgie*, August 16, 1884) has examined these organs in a number of individuals dead of tubercular affections. In nearly every case of pulmonary phthisis he found turbercles in the tonsils, while in those who had died of tuberculosis of other organs these bodies were healthy. The result of these investigations would seem to show that the tonsils become infected directly by the tuberculous matter in the sputa, since they were diseased only in those cases in which the lungs were affected. Tuberculosis of the tonsils seldom leads to extensive caseous degeneration or destruction of the organs. Small miliary tubercles and few bacilli are found.

Treatment of Pseudarthrosis.—In a monograph recently published in St. Petersburg, Dr. A. Karmiloff reviews the different methods of treatment of ununited fracture, and gives the indications for the employment of each. He regards irritation of the integument by iodine, blisters, etc., as of no value, except in cases of retarded consolidation merely. The method of rubbing together the ends of the bone was successful in about 10 per cent. of the reported cases. It is indicated only in those cases in which the opposing ends of the bone are thick and lie in close apposition. This procedure is not always a safe one, and has sometimes been followed by very serious consequences. Dieffenbach's method of inserting ivory pegs has resulted successfully in 43.5 per cent. of operations on the thigh and arm, and in 80 per cent. of operations on the forearm and leg. The author, however, believes this percentage is too high, many failures not having been reported. The method is only useful when the ends of the bone can be kept firmly in position, and when the tissues respond readily to slight irritation. Electro-puncture, the subcutaneous injection of chemical irritants, the insertion of needles into the tissues between the ends of the bone, and the pinning together of the fragments, are all procedures that the author regards with some favor, but which he considers less effectual than Dieffenbach's method. When the ends of the bone lie near each other, are perfectly movable and thinned down, and when the tissues seem to have lost the power of bone formation, Dr. Karmiloff regards resection as clearly indicated. The resected ends are to be held in close apposition by splints or suture.—*Centralblatt für Chirurgie*, August 9, 1884.

The Cause of Puerperal Septicæmia.—In a communication addressed to the Société des Sciences Médicales of Lyons, M. Arloing (*Lyon Médical*, August 3, 1884) claims to have isolated the microbe of puerperal septicæmia. The organisms are micrococci united in the form of long chains looking at first sight like bacilli. Inoculations of rabbits with cultures of the microbe caused death with symptoms of septic poisoning. In some cases fibrinous peritonitis was found after death. He concludes, from the experiments made by him, that the different forms of puerperal septicæmia are caused by the same agent, the particular form of the disease being due to the degree of activity of the microbe. Yet he does not maintain that this micro-organism is peculiar to the puerperal state, but only that at this time the conditions are favorable to its introduction and development.

Sclerosis in Plaques following Infectious Diseases.—According to Dr. Marie, infectious diseases, such as typhoid fever, small-pox, pneumonia, syphilis, etc., may give rise to consecutive paralyses caused by *sclérose en plaques*. The author reports twenty cases taken from various sources. This view of the nature of paralysis occurring during convalescence is somewhat novel and needs further confirmation before being accepted.—*Revista Clinica e Terapeutica*, August, 1884.

Honey as a Remedy for Small-pox.—A physician of Arequipa, Peru, writes to a local journal in praise of the virtues of honey in the treatment of small-pox. A child was attacked with what threatened to be a very severe form of the disease, but to the surprise of all began to mend within a few days, and passed through a speedy convalescence without any complications. In searching for a cause of this unusually rapid recovery, it was found that the patient, whenever left alone by his nurse, had helped himself to some honey which was standing in a jar near his bed. The remedy was then tried in two other cases occurring at about the same time, and with equally favorable result. The writer seemed to think that there was something more than a mere coincidence in these cases, and hoped that others would make a trial of this toothsome remedy in order to prove its efficacy.—*La Crònica Médica*, August 5, 1884.

Treatment of Enlarged Prostate.—M. Tripier directs attention to the possibility of reducing prostatic congestion by faradization. One electrode is to be introduced into the urethra and the other into the rectum. He has also had recourse to simple intra-rectal faradization. The sittings are of five minutes' duration, and the strength of the current is to be so as to cause no pain. For hypertrophy of the prostate the author makes use of suppositories of one and a half grain of iodide of potassium and one-tenth grain of muriate of morphia.—*Lyon Médical*, August 3, 1884.

The Condition of the Ovaries during Menstruation.—Dr. Meyer has made a number of bimanual examinations of the ovaries during the menstrual period to determine what changes they undergo at this time. In some cases he found an evident increase in size; in some no change was discoverable. While these organs are usually of a firm consistence, during menstruation they are found to be elastic. In some cases the ovaries were of a more rounded form, in others there were inequalities on the surface of the organ. Sometimes he could observe no change in shape, and sometimes there were changes in both organs, or again in only one.—*Lyon Médical*, August 10, 1884.

The Action of Phosphorus upon the Fœtus.—Dr. Igacushi Moritzi Miura, of Japan, has been conducting some experiments on rabbits and guinea-pigs to determine whether phosphorus given to the mother induces any changes in the fœtus. He found fatty degeneration of the liver in the mother thirty to forty hours after poisoning with phosphorus, and the same condition, but less marked, in the fœtus. He found gastro-adenitis in the fœtus as well as in the mother. Hence he concludes that phosphorus given to the mother can pass through the placenta and exert its injurious effects upon the fœtus also.—*Centralblatt für Klinische Medicin*, July 26, 1884.

Pernicious Anæmia in Children.—Dr. Kjellberg relates the case of a child five years old who was seized rather suddenly with headache and general languor. At the same time the skin became of a pale yellow, waxy appearance, the lips were pale, and the countenance had the appearance of suffering, although the body remained plump. Soon he had dyspnœa on the slightest exertion, palpitation of the heart, an anæmic murmur was audible in the vessels of the neck, and there were hemorrhages into the retina and under the skin. The blood was pale in color, and the number of red blood-corpuscles fell away from 900,000 to 571,000 per cubic millimetre. Death followed in six weeks, in spite of arsenic exhibited in moderate dose. At the autopsy there was extensive fatty degeneration of the heart, the brain was very anæmic, and the kidneys were fatty. There was no enlargement of the liver, spleen, or lymphatic glands. This, the author says, is the second case of pernicious anæmia in childhood that is known in pediatic literature.—*Centralblatt für Klinische Medicin*, July 26, 1884.

Diagnosis of Apparent Death.—The temperature of the skin in the living subject always rises during contraction of the muscle lying immediately beneath, but after death, even during the time that the muscular contractility to electrical stimulus is preserved, this increase of heat does not occur. Dr. Max Buch sees in this a valuable sign by which it can be determined whether life is extinct. The thermometer is to be placed upon the integument before and after muscular contraction has been excited by electricity, and if the mercury does not rise at the second trial he regards the patient as certainly dead.—*Deutsche Medicinal-Zeitung*, No. 37, 1884.

Miliary Aneurism of the Stomach.—Dr. Gallard has had an opportunity of seeing three cases of hæmatemesis from the rupture of miliary aneurisms of the stomach (*Deutsche Medicinal-Zeitung*, No. 37, 1884). The first case was that of a man, fifty-one years of age, who was suddenly seized with severe hemorrhage from the stomach and bowels. He had never suffered from any gastric trouble. Death occurred in a few days, and at the autopsy there was found a small tumor the size of a millet-seed, in which there was a little opening plugged with a clot of blood. It was ascertained by injection that this tumor was formed by an enlargement of a branch of the coronary artery. A month later Dr. Gallard received another patient who had suffered for two days from severe hæmatemesis. There was no history of a previous affection of the stomach. At the autopsy the same condition was found as in the first case. The third patient had been seized while upon the street with hemorrhage from the stomach. He had for a few days complained of loss of appetite and pain in the epigastrium. The next night the patient died, and at the autopsy there was seen a tumor the size of a bean on the greater curvature near the cardiac orifice. There was a perforation at the apex of the tumor through which the blood had escaped. The tumor lay directly over a small artery, but attempts at injection failed. The only case similar to these that has been reported is one of Dr. Douglas-Powel. But here, however, there was a tubercular ulceration of the stomach, so that the aneurism could only be regarded as of secondary origin.

Antipyrin in Diseases of Children.—Drs. Penzoldt and Sartorius have made a number of trials of antipyrin in the treatment of children's diseases, and report the following conclusions in the *Berliner Klinische Wochenschrift* of July 28, 1884: 1. Antipyrin is to be regarded as a very effectual remedy in the pyretic diseases of childhood. 2. In suitable dose it lowers the temperature several degrees, and the effects continue for several hours. 3. The pulse rate is never reduced in a degree corresponding to the fall of temperature. 4. The effect upon the general condition is usually good. 5. The only disturbances that it ever causes is occasionally vomiting. When this occurs the remedy may be given by the rectum. 6. Antipyrin should be given in three doses at intervals of an hour. Each dose should consist of as many decigrammes (one and a half grain) as the child has lived years. If this dose is insufficient, as may often be the case in small children, it should be increased a decigramme at a time until the desired effect is obtained. When administered by the rectum, a single dose of from three to six times as many decigrammes as the child counts years may be given. 7. When the use of the drug has been long continued the organism seems at times to become tolerant, and then the dose must be increased cautiously.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, September 13, 1884.

PROFESSOR VIRCHOW'S ADDRESS ON METAPLASIA.

We have received from our correspondent in Copenhagen the full text of Professor Virchow's address before the International Medical Congress, and are enabled to supplement the necessarily brief cabled report by a more complete abstract of the lecture. After referring to the older theories concerning the nature of the vital processes in health and disease, the author stated briefly his doctrine of cellular pathology and showed how it opposed Schwann's theory of the origin of cells from the blastema. The old theory of the identity of growth and nutrition is manifestly untenable. The end and aim of nutrition is self-preservation, while that of growth is increase of cells. When, in the latter process, two cells are formed from one, the old cell disappears, and thus we see that the plastic process, although productive, is, in a certain sense, also destructive. Thus there is a contradiction between the nutritive or trophic and the formative or plastic processes, which no amount of reasoning upon the materials affecting nutrition and growth can explain away. Because the same matter is used at one time for nutrition and at another for the increase of cells, it in no way follows that the processes in the two cases are identical, and still less that the cause of both nutrition and growth resides in this matter. All organic activity, the speaker insisted, resides within the cells. There is a wide difference between cellular nutrition and the nourishment of the individual. The former only begins where the latter ends. Living tissues may take up materials without using them in nutrition, as, for instance, the intestinal epithelium, and the hepatic cells take up fat during the process of digestion, but they soon give it off again. In the process called assimilation, in which the cells take up matters from the fluids and then form them into the necessary tissue materials, nutrition and growth seem to approach each other; but yet there is a distinction. The formation of tissue materials from nutritive materials is indeed a sort of plastic process, but the latter term must be more strictly limited to express the setting forth of new elements, a formation of new cells. Growth itself includes two processes, which must be kept distinct one from the other. There is hypertrophy, an increase in size of the individual cells, and hyperplasia, a true new formation whether of cells or nuclei; the one belongs to trophic, the other to plastic processes.

But there is another group of processes, more nearly related to the plastic than to the nutritive, and yet not in a strict sense plastic, as no new elements are formed. This is what the author called metaplasia, the distinguishing mark of which is the persistence of the cells while the character of the tissue is changed. Although metaplasia is the basis of many important pathological processes, it is not pathological *per se*. We see it exemplified in the formation of the bony framework of the body. In order to a right comprehension of the subject it is necessary to distinguish between the two processes embraced by the term ossification. There is first the formation of the osseous tissue, ossification properly so called, and there is also the formation of the complete bone, a true organ, and this is correctly designated osteogenesis. As regards ossification, it is right to say that the bone is formed as a rule from cartilage and, at a later stage, also from periosteum. But in osteogenesis there is a further process, the formation of the marrow, called by the speaker medullification. The marrow was formerly regarded as a sort of exudation filling up the medullary canal and the spaces in the spongy portion of the bone. But when the living bone in its totality came to be studied, it was recognized that marrow is as true a tissue as the bone, the cartilage, or the periosteum. We find three principal forms of marrow, the red, the yellow, and the gelatinous. These three forms, however, represent different conditions of the same thing; hence the marrow is a changeable tissue and presents a striking example of metaplasia. But this tissue is not only metaplastic, it is also of metaplastic origin. The greater part of that which fills up the centre of a fully developed bone was formerly osseous tissue. This tissue gives up its lime-salts, and the bone-corpuscles become changed into marrow-cells, their constitution is altered and softened. If this process assumes an excessive character we call it osteoporosis, and in a still more advanced degree, osteomalacia. But this is not the only mode of origin of the marrow, for it may be formed directly from cartilage. This fact was first discovered by Virchow while studying the development of the bones forming the base of the skull. He found that only a small portion of that part of the sphenoid bone forming the clivus Blumenbachii, which is cartilaginous at birth, undergoes direct ossification. The greater portion is transformed directly into marrow. It was here also that the author was enabled to follow the process of metaplasia of the small, red marrow-cells into large fat-cells, the change of red into yellow marrow. The transition of cartilage into marrow-cells occurs in the same way as does that of bone into marrow, with this difference, however, that, while the marrow from osseous tissue is permanent, the same substance formed from cartilage shows a marked tendency to ossification. So striking is this tendency, indeed, that perhaps the majority of observers regard ossification from cartilage as a secondary act, the first part of the process being a medullification. This is not always the case, however, for an examination of lateral sections of the epiphyseal cartilage in normal osteogenesis shows beyond question that the process here consists in a direct ossification of the cartilaginous tissue.

The development of bone is thus shown to furnish a striking example of a manifold metaplasia. How little the simple nutritive standpoint serves to explain this metaplasia is well shown by the results of the studies

made of the formation of the spongy tissue during the last decade. These have shown that the number and the direction of the bony trabeculæ depend upon the pressure and traction forces working from without. The spongy tissue arises from a formation, not of the osseous trabeculæ, but of marrow which dissolves out the bone by a process of metaplasia in some places and, so to speak, spares it in others. The main part of the process consists in a medullification rather than in an ossification. These examples must have the effect of directing more attention than was formerly given to the metaplastic character of many processes, the exact significance of which can only be grasped by regarding them in this light. Without such an explanation, indeed, the etiology of these various processes may be understood in a general way, but beyond this we could not go. It is very important, for example, to know that syphilis may cause sclerosis of the long bones and also osteoporosis, but it is of still greater moment to recognize the fact that these two conditions may be but different stages of the same process.

These various metaplasias in osseous tissue are by no means of equal significance, and even the same form of metaplasia must be judged differently under differing circumstances. The secondary formation of marrow from compact bone substance forms in normal development the final stage of osteogenesis, and we may thus regard it as a progressive process. But in osteomalacia, on the other hand, in which medullification surpasses the normal limits, we derive the impression of a destructive and regressive process. Wherefore it follows that a prognostic judgment upon these metaplastic changes cannot be based upon a simple knowledge of these processes, but must rest upon a consideration of all the circumstances in which the organ is placed.

Professor Virchow then discussed the metaplasia of adipose tissue. The changes here are rather monotonous in character, the fatty being metamorphosed most frequently into mucous tissue, but the study of them is not without interest as bearing upon the formation of some forms of tumor. In this kind of metaplasia the fat is removed from the cells, but the cells remain and generate mucus. This, however, is not distinct from the cells; it is not, strictly speaking, secreted, but remains as an integral part of the tissue. The process is a return of the fatty tissue to the same tissue from which it is formed in embryonic development. It is not emaciation, for there is evidently a difference between simple atrophy of fatty tissue and the formation of mucous tissue by metaplasia. A lipoma may arise from adipose tissue by partial hyperplasia. Sometimes lipomata present numerous points of gelatinous formation, and there are even tumors growing from adipose tissue which are gelatinous throughout their whole extent. These tumors are called by Virchow myxomata. Since mucous tissue is normally embryonal, one might say in a certain sense that myxomata are composed of embryonic tissue; indeed that tumor, called by the author myxoma of the villi of the chorion, the hydatidiform mole, is wholly embryonal. But every myxoma is not of congenital origin, for besides the primary embryonal mucous tissue there is, as we have seen, a secondary tissue of this kind formed in adults by metaplasia, and from which myxomata are developed by hyperplasia. The author then spoke of tumors formed from nævi which may be said to be embryonal tissue, and of enchondromata arising from little islets of cartilage forgotten in the process of ossification, which are certainly of non-congenital origin. And he took occasion here to refute the theory of Cohnheim, who regards all tumors as originating from unchanged embryonic tissue.

Hitherto the argument had been confined to metaplasia between tissues of a similar character, but in concluding the author touched briefly upon that occurring in tissues belonging to different categories. He had never seen an instance of the formation of connective tissue from epithelial elements, but was convinced that the converse does obtain. He did not believe, as is maintained by some, that the white blood-corpuscles were capable of producing every form of new tissue, or, in other words, that they were possessed of the property of absolute metaplasia, but thought that their powers in this respect were limited.

Of course, so difficult a problem as the possibility of metaplasia in the sense of dissimilar tissue production cannot be regarded as solved because affirmed by even so high an authority as Professor Virchow. Indeed, the learned speaker himself disclaimed any such assumption, and expressed simply his gratification that he had been instrumental in directing the attention of investigators to this point, and he hoped that their labors would be simplified somewhat at the start by an acquaintance with the less complicated forms of metaplasia which they had just been considering.

WHAT IS THE CHOLERA MICROBE?

The nomenclature of bacteriology, as is always the case in every new science, is by no means satisfactory. The discoverer of each new form of micro-organic life has given it whatever name best suited his fancy, and while this was doubtless satisfactory to the word-coiner, it resulted in a confusion of terms sufficient to appal even the most stout-hearted tyro in bacterial studies. Cohn has done much by his classification to simplify the question, and although his system is by no means perfect, it has been adopted by most of the German writers, Koch among the rest. Yet the latter seems to have departed from this nomenclature in one notable instance at least, in the designation, namely, of the supposed cholera microbe. He has called it the comma-bacillus. The qualifying word "comma" was not happily chosen, for it suggests an organism of curved form with a head and a tapering extremity, whereas the cholera microbe is of equal size throughout with no distinction of its extremities. But more than this, as Koch himself says, the "bacillus" is probably not a bacillus at all, but rather a spirillum. Indeed, there are many points of close resemblance between the spirilla and the micro-organisms found in the dejections of cholera patients.

Dr. Mühlhäuser, of Speier, has recently made a study of spirilla, embodying his results in an interesting article appearing in *Virchow's Archiv*, No. 1, 1884. This organism he describes as existing in the form of a long, fine thread, twisted into a number of spiral turns. The spirals are of equal size and may vary in number from two

to ten or more. There is no appearance of head or tail, each end of the spiral thread being of equal thickness. These bodies are possessed of the power of independent motion, turning upon themselves like the screw of a propeller. The spirillum seems to be enclosed in a sheath, like the axis cylinder, which terminates at each extremity in a cilia-like prolongation. It is probably to these cilia that the body owes its power of motion. The spirilla grow by direct increase in length, adding coil upon coil until the number may reach a dozen or more. The larger the number of spirals the slower is the motion.

Spirilla are reproduced by fission, and never by the production of spores. And here begins the likeness between them and the so-called comma-bacilli. The latter, Koch insists, are never reproduced by spores, the parent microbe must be present and alive, otherwise no reproduction of organisms can occur. Another point of resemblance lies in the weak powers of resistance possessed by these organisms. Koch says that drying kills the cholera microbe with absolute certainty, and Mühlhäuser says the same of the spirillum. The latter is even killed by sunlight, but seems not to be injuriously affected by cold, and this fact is also affirmed of the cholera germ, which has been seen to revive even after having been frozen. Both these forms of micro-organisms depend upon oxygen for their existence, a peculiarity which separates them sharply from many other forms of bacterial life. Mühlhäuser saw in some fresh culture-fluids certain minute shapes which seemed to be straight and resembled the bacterium termo, but which he found on closer inspection to be bent, and to be spirilla of but two coils, thus resembling also in form the cholera germ. Another peculiarity of the spirilla was that they were sometimes joined together, end to end, like links of a chain. Koch also saw this union in the case of the cholera microbes, two being joined in the shape of an 'S,' or at times there were longer strings, looking like the spirals of a corkscrew. Of course, in this case the resemblance is only in outward form and may be apparent only, but the other points—the absence of spores, the slight power of resistance to outward influences, cold alone excepted, and their dependence upon oxygen for existence—would indicate a near relationship, even though they may not be members of the same family.

THYMOL IN THE TREATMENT OF CHOLERA.

Professor Bozzolo has written a letter to the public press in Italy, advocating thymol on theoretical grounds as a remedy for cholera. If it be true, he says, that cholera is due to the presence of micro-organisms in the intestinal canal; that these organisms are developed in this part because they find there an alkaline fluid favorable to their growth; and that acids kill them, or at least hinder their further development, then the problem is to find a slightly soluble acid, and strongly antiseptic substance which is, in large quantities, innocuous to the human organism, and which will pass into the intestines without suffering appreciable change in the stomach. These valuable properties, the learned professor maintains, are possessed by thymol. This substance may be given, he says, without danger, in the dose of three drachms a day, divided in capsules containing seven and a half grains each. Judging from the recent telegraphic reports of the ravages of the cholera in Italy, we are forced to conclude either that this remedy has not been tried to any great extent, or else that it has been proven ineffectual.

THE PREVALENCE OF TYPHOID FEVER IN NEW YORK.

Some statements have been made in the daily press to the effect that typhoid fever is prevailing more than usually in this city. Such is not the case, however, according to the latest reports. There is always some increase in the disease in the fall, and the mortality statistics show that the deaths therefrom are one-third greater in the last quarter of the year than in the first. During the past month of August the number of cases has been from 24 to 34 per week, and in the first week of September the number reported was 48.

The total number of cases in August was 140, while a year ago the number in the same month was 244. In September, 1883, the cases reached a total of 303 for the month, or 76 per week. So that typhoid fever now prevails a little more than in 1882, but it is much less than in 1883.

At the present time, with so many persons returning from the country, a certain proportion of the cases are probably imported. Then the settling again in a house whose drains and pipes have not been flushed for some time is a thing not always without danger. A timely caution from the family physician at present might be of much service.

THE BAD SANITARY CONDITIONS OF THE GREELY PARTY WHILE AT CAPE SABINE.

According to Dr. Green's report of the medical history of the survivors of the Lady Franklin expedition, published in last week's Record, it seems that this party spent their long winter night in a miserable hovel 25 feet long by 17 feet wide and 4 feet high, making the cubic air space 1,700 feet. In this the twenty-four members of the party lived all winter, having a cubic air allowance of about seventy feet for each man. "The whole party," it is said, "could barely squeeze in and lie at length, two or three being obliged to occupy the same sleeping bag." There were, it appears, certain vent-holes in the roof, which were sometimes stuffed with rags, and on one occasion the whole company came near perishing of asphyxia by the carbonic acid from an alcohol lamp which was burning in the hut while the vent-holes were stopped. Doubtless the sufferings and mortality of the party were augmented by the evil effects of bad air. It is well known that between four and five hundred cubic feet of air pass through the lungs daily, and in the same period about twenty-three cubic feet of oxygen are absorbed, and that the size of an apartment in which persons are confined should be such, that there shall not be less than eight hundred cubic feet for each person occupying the room. A multitude of instances illustrative of the fatal effects of neglect of this precaution are on record, the most notable of which is that of the "Black Hole of Calcutta," an account of which may be found in any text-book on physiology. The baneful results of imperfect hæmatosis from bad ventilation are familiar to all medical readers,

and it would appear, by analyzing the morbid phenomena presented by various members of the expedition, and so well described by Dr. Green, that the party when found were suffering almost as much from want of oxygen, and from accumulation of carbonic acid in their systems, as from deprivation of food. Add to this that they had long ceased to bathe themselves or take regular exercise (except perhaps Long and Brainard, who were the most healthy of the lot), and that they were extricated from appalling filth, and the wonder is that there were any survivors to tell the story.

MENSTRUATION IN WOMEN AND IN ANIMALS.

A HARVARD medical student, in the *Boston Medical and Surgical Journal*, August 28, 1884, has an interesting article on the phenomenon of menstruation in women and of heat in animals. According to this writer, "woman is more different from the man (*sic*) than the brute females are from their males, and the reproductive processes are intensified in her." In woman the menstrual period "is the period of absent sexual desire, and is by no means contemporaneous with ovulation." "The human intelligence has rendered woman sexually independent of the heat; sexual congress is permitted at any time, and therefore she is subject to a condition not prevalent in the brute animals; she is liable to conceive at any time." This writer goes on to observe that, in view of the possibility of pregnancy at any time, and the immediate demands upon her nutritive force which would come from such an event, "woman has to be *run* at a higher pressure (*sic*) than is necessary for the needs of the non-pregnant female." This lucid explanation is supplemented further on by the statement that, since the human female "is *run* at such high pressure, frequent overflows of nutritive material are necessary in the non-pregnant women, and these overflows take place at certain periods of genital hyperæmia inherited from the lower animals, that is, at the menses. That is to say, the reproductive side of menstruation is emphasized in woman, the sexual side in brutes."

Despite certain infelicities of style, the present status of the subject is fairly represented in the article. The ovulation theory is no longer tenable, as cases are on record of menstruation after double ovariotomy, of ovulation without menstruation, and of menstruation without ovulation. Instances of conception fifteen days or more after coitus are numerous. Stedman has reported a case where "a woman had menstruated regularly to the time of her death, but whose ovaries were found cystic and atrophied." It would seem then that there is very strong evidence against the ovaries being the source of the menstrual impulse, and the writer asks whether this impulse may not come from the general system. He points out the fact that fear, horror, and violent emotions, in general, are known to have an immediate effect on menstruation in many cases. "The influence of the mammæ is marked. Dr. Campbell cites two cases of premature menstruation in children caused by mammary inflammation." Change of climate often suppresses menstruation; a sea-voyage often delays or hastens the next period; anæmia is a most fruitful cause of amenorrhœa, and so, alienists have told us, is a mental disease. The writer takes up the recent theory propounded by Kindrat and Williams, and defended by Dr. Chadwick in a former number of the *North American Review*, that "menstruation is neither a congestion nor a species of erection, but a molecular disintegration of the mucous membrane of the uterus, followed by hemorrhage." In other words, the uterine mucus undergoes disintegration and exfoliates with each menstrual period; menstruation is then a sort of disappointed pregnancy. "When conception takes place a process of nine months or more of uterine increase is gone through, followed by fatty degeneration and desquamation in the puerperal state. When no conception, the process is completed in a little over a week." The observations of Moricke and Wyder seem to disprove this view; Moricke showed, by scraping with a curette the uterine mucous membrane of his menstruating patients, that there was no destruction, partial or total, of the mucous membrane, and no fatty degeneration; the bleeding, according to him, is due to diapedesis. Wyder, by a series of careful observations also arrived at the same conclusion, that in menstruation there is no denudation of the mucous membrane.

With respect to theories of menstruation this writer thinks that we are more badly off than we were ten years ago, when this physiological phenomenon was better explained than it can be to-day, in the light of all the facts.

News of the Week.

DR. VAN DER VEER, of Albany, gave a reception at his home in honor of Mr. Lawson Tait, of London.

IN MEMORY OF CIVIALE.—The municipal council of Paris has voted to give the name of Civiale to one of the streets in Paris.

A NEW EMERGENCY HOSPITAL FOR BELLEVUE is soon to be established in one of the down-town districts. This will relieve some of the work of the Chambers Street Hospital.

PARIS IS TO HAVE A BABY SHOW.—Artists and doctors are to be on the committee of judges, and healthfulness is to be considered as well as beauty in giving the awards.

CLAIMANTS TO PRIORITY IN THE DISCOVERY OF THE CHOLERA BACILLUS.—The number of these is increasing weekly. Besides the names of Dr. Bristowe and Professor Pacini, a Polish paper now claims the honor for Dr. Klodzianowski. The *Lancet* now brings up Dr. A. H. Hassall, who claims to have discovered the bacillus thirty years ago.

THE NEXT INTERNATIONAL MEDICAL CONGRESS.—Referring to its next place of meeting the *British Medical Journal* says: "We may be sure that our transatlantic cousins will leave nothing undone to make the next meeting as successful as the last two, if indeed they do not succeed in eclipsing former achievements; however this may be, the announcement will be received with great pleasure in this country, where we have learned to set a high value on the work done by the medical profession in the United States."

MEDICAL CHANGES IN BERLIN.—Owing in part to the appointment of Professor Schweninger as a member

of the Imperial Board of Health, the Director, Dr. Struck, has resigned. Dr. Koch has refused to be his successor, and has also withdrawn from the Board, being content with his position as Professor of Hygiene and Director of the Hygienic Institute. Dr. Julius Wolf has been made Extraordinary Professor of Surgery, and Dr. Mendel Extraordinary Professor of Psychiatry.

Ozone and Cholera.—During the cholera epidemic at Marseilles, ozone disappeared from the atmosphere. When it reappeared, after a southwest wind, the cholera mortality fell. It is not easy to produce ozone; there are many methods recommended, but they are all mostly worthless. M. Onimus only admits one method, electrifying the oxygen of the air either by a Ruhmkorff's induction machine and Berthelot's tubes, or by an ordinary electric machine; at the Pharo hospital M. Onimus adopted the latter method. The ozonoscopic papers testified that ozone was produced. Its actual therapeutic properties could not be determined, as the usual treatment was observed conjointly. The mortality was low in those wards where ozone was artificially produced.

The Elevation of a Quack.—It appears that Berlin medical circles are much disturbed over the elevation of Dr. Schweninger, Bismarck's Leibarzt, to a position in the Medical Faculty of the Berlin University. Schweninger had no scientific or even social standing amongst the profession previous to his success with Bismarck, and the correspondent of the *Allgemeiner Wiener Medicinische Zeitung* affirms that if he presented himself for admission to the Berlin Medical Society now he would be undoubtedly rejected.

Schweninger was formerly connected with the Munich Faculty, but was obliged to leave somewhat under a cloud. He is claimed to have advertised and applied a so-called "Schweninger-cure" for obesity, fatty heart, etc. This "cure," which he applied to Bismarck, is substantially that laid down by Professor Oertel in "Ziemssen's Handbuch der Therapie der Kreislaufstörungen, Feltherz," etc.

Despite the unpleasant pushing forward of the obnoxious quack, the Berlin medical journals are forced to keep very quiet, and it is only through Berlin correspondence that the true state of feeling is made known.

Death of Professor J. Cohnheim.—We regret to learn of the death of Professor J. Cohnheim, at the comparatively early age of forty-six. He died of gout complicated with some renal trouble. Professor Cohnheim was one of the most distinguished of the pupils of Virchow, whose assistant, in the Berlin Pathological Institute, he was from 1864 to 1868. In 1868 he was appointed ordinary Professor of Pathology at Kiel, and, in 1872 he preceded Waldeyer in a similar capacity at Breslau. It was there that he made his well-known researches on the changes produced by embolism, and on the escape of the white blood-corpuscles through the walls of the vessels in inflammation. In 1876 he succeeded Wagner in the chair of General Pathology and Pathological Anatomy in the University of Leipsic, and held that professorship up to the time of his death.

The Académie de Medecine of Paris continues its session through the summer. At its meeting on August 19th, the subject of cholera was discussed. M. Bouley read a paper for M. Chauveau on gangrenous septicæmia, in which it was shown that gangrenous septicæmia in man is identical with that in animals, and depends upon a *microbe aérobie*, which is probably only the septic vibrio of Pasteur.

A Place for Cholera to Locate.—One-fourth of the whole population of the State of New Jersey drink the water of the Passaic River, taken from a point where the tide, laden with the sewage of Newark's 140,000 people, flows up and meets the downward current bearing the sewage and factory refuse of 60,000 dwellers in Paterson and other cities on its banks a few miles above. The city of Passaic now proposes, says the *Sanitary Engineer*, to add its quota of sewage to the river by establishing a system of drainage. The water of the Passaic has been condemned as dangerous long ago. But in view of a prospective visit of cholera the matter becomes really serious and of interest to others than those living by the polluted river. The establishment of pumping works on the Passaic above all source of pollution is the remedial measure urged by our contemporary, and it is one that has been approved of by competent engineers.

Alleged Successful Inoculation of Lower Animals with Cholera.—A cablegram from London says that Drs. Reitsch and Ricati, of Marseilles, claim to have successfully inoculated lower animals with the cholera microbe. The animals died with choleraic symptoms. Remembering the great ease with which septic phenomena can be produced in certain lower animals, the reports of successful inoculations must be received with skepticism until full details are given.

The Paradise of Eclectics.—A writer in the *Kansas Medical Journal* grows enthusiastic over the present and future of Eclecticism in Kansas. The Eclectics in that State number nearly six hundred. "They do not," he says, "seek seclusion in rural districts generally, but occupy lucrative positions in cities and country towns, and in comparison with other industrial classes they are thrifty, diligent, have nice homes, pretty wives, sons, and daughters (so we think), wear good clothes, drive fine horses, own miles of prairie, bank stocks, meet the difficulties and enjoy the incidents that go to make up a busy, active life." The State Society has obtained a charter for a medical college.

The Canada Medical Association.—We learn from a correspondent that the annual meeting of this Association at Montreal, just previous to the meeting of the British Association, was unusually well attended and successful. We have received, too late for publication, the address of the president, Dr. M. Sullivan, of Kingston. It was a most able effort, and contained a great deal of solid statistical matter, as well as of practical suggestion regarding the medical affairs of Canada.

The Cholera.—The cholera has attacked Naples with a severity far surpassing that with which it visited Marseilles, or even Toulon. On September 8th there were eight hundred fresh cases and three hundred deaths within twenty-four hours. Some sixteen provinces of Italy have now been attacked. In most of these, however, the daily number of fresh cases is not large, varying from one or two to fifteen or thirty. The disease is spreading slowly in Spain, but is evidently dying out at

Toulon and Marseilles. The total number of deaths from cholera up to date is about six thousand, which means that there have, since June, been from twelve thousand to fifteen thousand cases of the disease.

Reviews and Notices.

Practical Manual of Diseases of Women and Uterine Therapeutics, for Students and Practitioners. By H. Macnaughton Jones, M.D., M.C.H., F.R.C.S. I. and E. Examiner in Obstetrics Royal University of Ireland, Fellow of the Academy of Medicine in Ireland, etc. New York: D. Appleton & Co. 1884. 12mo. pp. 392.

It is seldom that we see a book so completely fill its avowed mission as does the one before us. It is practical from beginning to end, and cannot fail to be appreciated by the readers for whom it is intended. The author's style is terse and perspicuous, and he has the enviable faculty of giving the learner a clear insight of his methods and reasons for treatment. Prepared for the practitioner, this little work deals only with his every-day wants in ordinary family practice. Every one is compelled to treat uterine disease who does any general business whatever, and should become acquainted with the minor operations thereto pertaining. The book before us covers this ground completely, and we have nothing to offer in the way of criticism. The illustrations of diseased conditions and of instruments are numerous and appropriate.

Diphtheria, Croup, Etc.; or, The Membranous Diseases: Their Nature, History, Causes, and Treatment; with a Review of the Prevailing Theories and Practice of the Medical Profession; also a Delineation of the New Chloral Hydrate Method of Treating the Same, its Superior Success, and its Title to be considered a Specific. By C. B. Galentin, M.D. Cleveland, O.: Printed at the Publishing House of the Evangelical Association. 1884.

The title of this book sufficiently indicates the object of the writer in giving it to the world. The author states that since 1875, when he first began to use chloral in the treatment of diphtheria, he has given it in over five hundred well-marked cases of the disease, with a mortality of less than two per cent. Prior to that time, when employing the ordinary treatment, he had encountered a mortality of from 25 to 33½ per cent. The chloral is given in small repeated doses with the object of inducing and maintaining a quiet somnolent state. A moderate hypnotic effect is, in the author's experience, essential to the best results, as at this point the temperature and pulse-rate are reduced, and worry, headache, and nausea disappear. This effect is also, he states, an indication that the remedy has been absorbed into the blood in sufficient quantity to produce upon it specific effects.

A Treatise on Ophthalmology for the General Practitioner. Illustrated. By Adolf Alt, M.D. Chicago, St. Louis, & Atlanta: J. H. Chambers & Co. 1884.

This book, as its title implies, is intended solely for the general practitioner. Its object, as stated in the preface, is to give the general practitioner a clear idea of the principles of ophthalmology, together with so much only of its practice as he might be reasonably justified in attempting. With this aim in view the author has succeeded in producing a really valuable work, one which may be perused with profit by the non-specialist, and which he will not be forced to lay aside because overburdened with details relating to subjects of little or no use to him. The work contains numerous illustrations which, though rather coarse in their execution, are yet sufficiently clear to answer the purpose intended. The book is neatly printed on good paper and will be found a valuable addition to the library of the general practitioner.

Fat and Blood: An Essay on the Treatment of Certain Forms of Neurasthenia and Hysteria. By S. Weir Mitchell, M.D. Third edition. Philadelphia: J. B. Lippincott & Co. 1884.

The author states in his preface that he has, in the present edition, rewritten parts of the book, and has added many practical hints, particularly with regard to the treatment of obesity and the use of milk. Dr. Mitchell's method of treating certain classes of nervous invalids is now well known and has received substantial endorsement on both sides of the Atlantic. For our part, we believe that the method advocated is an immense addition to therapeutics, and one whose value is yet not sufficiently appreciated. At the time, we are quite aware that the proper cases must be selected, and that treatment must be conducted with great care and judgment. The author wisely concludes his book with the expression of fear lest his method now be misused or misapplied.

Text-Book of Medical Jurisprudence and Toxicology. By John J. Reese, M.D., Professor of Medical Jurisprudence and Toxicology in the University of Pennsylvania, etc. Philadelphia: Blakiston, Son & Co. 1884. 12mo, pp. 597.

Professor Reese is so well known as a skilled medical jurist that his authorship of any work virtually guarantees the thoroughness and practical character of the latter. And such is the case in the book before us. A very extensive field is travelled over by one acquainted with all its parts, and all the main and essential landmarks are plainly pointed out to the reader. We might call these the essentials for the study of medical jurisprudence. The subject is skeletonized, condensed, and made thoroughly up to the wants of the general medical practitioner, and the requirements of prosecuting and defending attorneys. If any section deserves more distinction than any other as to intrinsic excellence, it is that on toxicology. This part of the book comprises the best outline of the subject in a given space that can be found anywhere. As a whole, the work is everything it promises and more, and considering its size, condensation, and practical character, it is by far the most useful one for ready reference that we have met with. It it well printed and neatly bound.

Medical German. A Manual Designed to Aid Physicians in their Intercourse with German Patients and in Reading Medical Works and Publications in the German Language. By Solomon Deutsch, A.M., Ph.D. New York: J. H. Vail & Co. 1884. Pp. 336.

The first division of this book contains an extensive collection of words and phrases that pertain to medicine in all its branches. The second division consists of conversations supposed to be held with a sick patient, and it seems to cover every imaginable morbid condition. There is a very complete German-English index appended.

The book is designed to meet the wants of physicians who are learning German, and who have to deal with German patients. In this respect it fills an unoccupied niche and will prove a most useful publication. It conflicts in no way with Cutter's Medical German Dictionary, which contains a very much more copious vocabulary. The book is well printed and neatly bound in flexible covers.

The Theory and Practice of Medicine. By Frederick T. Roberts, M.D., B.Sc., F.R.C.P. With Illustrations. Fifth American edition. Philadelphia: P. Blakiston, Son & Co. 1884. Pp. 1008.

This standard work has now reached its fifth edition, a sufficient endorsement of its excellence to make the reviewer feel that his task is a superfluous one. In the present edition the subjects of diseases of the nervous system and diseases of the skin have received especial

attention, and the chapters bearing thereon have been rearranged and to a large extent rewritten.

Perhaps the most conspicuous of the valuable features of the work is its comprehensiveness, the very large field that it covers within the single volume. If we were to make any criticism on the other hand, it would be that too much is attempted, and that the author fails to possess what might be called the medical perspective. That is to say, he does not assign his space in strict accordance with the relative importance of the subjects. The book, as a whole, is weak in its pathology.

Nevertheless it deservedly takes a high place among the standard treatises on the practice of medicine.

An Introduction to Pathology and Morbid Anatomy. By T. Henry Green, M.D., London. Fifth American from the sixth revised and enlarged English edition. With 150 Engravings. Philadelphia: Henry C. Lea's Son & Co. 1884.

The present edition of this standard work has been considerably revised. The introductory chapter on cells, and the etiology of disease, and the chapters on tumors, regenerations, septicæmia and pyæmia, and on vegetable parasites are entirely the work of Mr. Stanley Boyd. They are very well written and do the author credit. The chapter on vegetable parasites in particular is one of the best presentations of the subject which we have seen, though it does not differ greatly from that in Ziegler.

The chapters on tuberculosis and phthisis would bear rewriting in the light of modern mycology. Dr. Green's work is more elementary and less critical than Ziegler's.

It serves all the better, however, on this account, as a text-book for students.

Sexual Neurasthenia. Its Hygiene, Causes, Symptoms, and Treatment, with a Chapter on Diet for the Nervous. By George M. Beard, A.M., M.D. [Posthumous Manuscript.] Edited by A. D. Rockwell, A.M., M.D. New York: E. B. Treat. 1884. Pp. 270.

To those numerous readers of the late Dr. Beard's work who admired the charm and suggestiveness of his writings the present posthumous volume will be examined with great interest. It will be found that the chapters here given possess the same attractiveness which attached to all the author's writings, and he who begins to read will be slow to lay down the book before it is finished. The first two chapters comprise an introduction and a discussion of the nature and varieties of neurasthenia. In them Dr. Beard has stated clearly and succinctly his peculiar views regarding the nature of nervous exhaustion and its relation to the functions of the body. He applies here, also to functional nervous disturbances, the laws of evolution and devolution, or dissolution, using the same line of reasoning which Hughlings Jackson employed in a series of lectures delivered in London last winter.

These first two chapters are decidedly the best in the book, and furthermore, are among the best pieces of medical writing ever produced by an American physician.

The remaining chapters contain much that is true with some that is incorrect or commonplace. In practically working out his principles, Dr. Beard was sometimes hasty and superficial. His diet for the nervous is too fanciful, and his description of the evolution of the sexual sense amounts to little. His chapter on sexual hygiene is excellent and correct, but he states what is generally known and generally accepted.

The illustrative cases deserve attention. They are many of them most curious histories, and a perusal of them will give some idea of the peculiar class of cases which the author attracted to himself.

Though of a philosophic, and as many would say, an impractical mind, Dr. Beard was a successful therapeutist, having great resources and thorough confidence in himself. The chapter on treatment is instructive, therefore, but every physician of experience will appreciate that it was the man behind the therapeutical armamentarium which accomplished the work.

Dr. Beard's book betrays some signs of incompleteness, and doubtless it would have been added to, and changed if the author had been spared. As it is, however, it shows well both the faults and merits of the author. And not the least among the latter is the perfect cleanliness and absence of pruriency in the manner with which a delicate subject is treated.

Work and Worry, from a Medical Point of View. By W. Henry Kesteven, M.R.C.S., L.S.A. London: Diprose & Bateman, Lincoln's Inn Fields. 1884.

This is a very pleasantly written and suggestive essay on the evil effects of worry. By work the author means only that labor which is entered upon and carried through with heart and mind and soul. And all distasteful and unpleasant labor he relegates to the category of worry. Accepting such a definition of terms, we fear there are few men, however favorably circumstanced, who have not to undergo nearly as much worry as work in the course of a day. For no labor, however pleasant in the main, is throughout and entirely free from annoyances and disagreeable interjections. Nevertheless, we can do much, if we set our minds upon it, to make almost any kind of labor less unpleasant than it would otherwise be, and thus go far to convert our worry into work. The little brochure is quaintly printed and bound, and corresponds to its external dress to the style of the author.

Obituary.

PROFESSOR ROBERT E. ROGERS, M.D.,

PHILADELPHIA, PA.

Dr. Robert Empie Rogers, a prominent physician and a leading teacher of chemistry, of Philadelphia, died there on September 6th. He was born in Baltimore, Md., in 1814, and after a careful preliminary education he studied and was graduated as an M.D. from the University of Pennsylvania in 1836. From 1844 to 1852 he was Professor of Chemistry at that University, and assisted his brother, J. B. Rogers, in preparing his edition of "Turner's Chemistry," and on the death of that brother he succeeded him as Professor of Chemistry in the Medical Department of the University of Pennsylvania. In 1877 he resigned this position, and accepted a similar one in the Jefferson Medical College, in Philadelphia. He contributed to the *Journal of the Franklin Institute*, took part with his brothers in the geological surveys of Virginia and Pennsylvania, and edited the American reprint of "C. G. Lehman's Physiological Chemistry," 1855.

JACOB H. STEWART, M.D.,

ST. PAUL, MINN.

Dr. Jacob H. Stewart, a prominent physician of St. Paul, Minn., died of apoplexy, August 25th, ult., aged fifty-six years. He was educated at the Academy in Peekskill, N. Y., where his father, Dr. Philander H. Stewart, resided; he afterward entered Yale College, remaining there three years, and finally graduated at the University Medical College in 1851. In 1855 he settled in St. Paul, Minn.

In 1861, at the breaking our of the war, he went as surgeon of the First Minnesota Regiment. While attending the wounded on the Bull Run battle-field he was taken prisoner and confined in Richmond jail. Being paroled, he returned to St. Paul and became examiner for recruits. He was elected mayor of St. Paul in 1864 and again in 1869, 1871, and 1873. In 1876 he was elected to Congress, and in 1879 was appointed by President Hayes Surveyor-General of Minnesota. He leaves a widow and three children, one of whom, Dr. Jacob H., is at present perfecting his studies in this city.

Reports of Societies.

International Medical Congress.

EIGHTH SESSION.

Held at Copenhagen, Denmark, August 10–16, 1884.

REPORTS OF SECTIONS.

(Special Report for THE MEDICAL RECORD.)

SECTION ON MEDICINE.

MONDAY, AUGUST 11TH—FIRST DAY.

THE section was called to order by the Chairman, PROFESSOR F. TRIER, who briefly reviewed the forthcoming work of the members. He regretted the absence of Professor Grainger Stewart, and announced that the following gentlemen had been nominated as

HONORARY PRESIDENTS:

Drs. Bouchard and Jaccoud, of Paris; Lépine, of Lyons; Liebreich, of Berlin; Liebermeister, of Tübingen; Biermer, of Breslau; Pribram, of Prague; R. Bennett, of London; H. Acland, of Oxford; Austin Flint, of New York; Tommasi Crudeli, of Rome; and Rosenstein, of Leyden.

SECRETARIES:

Dr. Madsen, of Copenhagen, Secretary-General; and Drs. Leyfert, of Wurtzburg; Daremberg, of Mentone; I. Owen, of London, additional secretaries.

DR. S. LAACHE, of Christiania, then read a paper on

THE VALUE OF RECENT RESEARCHES ON BLOOD-CORPUSCLES IN THE PATHOLOGY OF ANÆMIC AND LEUCÆMIC DISEASES.

The speaker said that, owing to the labors of Vierordt, Welcker, Malassez, and Hayem, we were now in possession of a method by which the clinician was enabled to determine with tolerable exactness, not only the relative number of the blood-corpuscles, but also the pigmentary powers of the blood.

It has been determined that, in

ANÆMIA FOLLOWING HEMORRHAGE,

the number of red blood-corpuscles may be reduced below fifty per cent. without causing immediate death or rendering impossible a *restitutio ad integrum*. In the process of regeneration, the formation of new corpuscles proceeds more rapidly, as a rule, than does that of the hæmoglobin.

According to the condition of the red blood-globules, we recognize two forms of

CHLOROSIS.

In the first form, pseudochlorosis, there is but little, if any, change in the red corpuscles. In the second form, the true chlorosis, these bodies have undergone an undoubted, and often very marked, alteration. Here, not only the coloring properties of the blood, but also the number of the corpuscles are reduced, the former, however, in the greatest degree.

This division of chlorosis is of practical value, as it is in the second variety, true chlorosis, that iron exerts its well-known therapeutical action. In

PERNICIOUS ANÆMIA

the number of red globules may sink below 500,000 per cubic millimetre without causing immediate death or destroying all chances of recovery. A peculiarity in this disease is, that the red corpuscles are on an average larger and contain more hæmoglobin than normal.

While the relations of the white blood-corpuscles in the above conditions are not constant, their increase in number is the predominating symptom in

LEUCÆMIA.

Their size, however, is variable. The red corpuscles may not be altered, even in advanced stages of the disease, and the decrease in number, even when it occurs, never reaches such an extreme degree in the three first-mentioned affections. Arsenic exerts a destructive action upon the white globules.

SIR RISDEN BENNETT, of London, took the Chair while PROFESSOR AUSTIN FLINT, of New York, read a paper on

A UNIFORM NOMENCLATURE OF AUSCULTATORY SOUNDS IN THE DIAGNOSIS OF DISEASES OF THE CHEST.

At the meeting of the International Medical Congress, in London, in August, 1881, the following resolution was adopted by the Section on Medicine:

"*Resolved*, That a Committee be appointed to report on a uniform nomenclature of auscultatory sounds in the diagnosis of diseases of the chest."

The following were appointed members of this Committee; Professors Austin Flint, of New York; Ewald, of Berlin; D'Espine, of Geneva; and Drs. Douglas Powel and F. A. Mahomed, of London.

At a meeting of the Committee, in London, it was agreed that each member should send his report to the Chairman, who would compare them and submit the results of such comparison to the Section on Medicine, at the meeting of the Congress in Copenhagen. Dr. Flint placed a

COMPARATIVE TABLE OF THE DIFFERENT LISTS

where it could be seen by the members, and then presented his report upon the points of difference and agreement in these several lists. An approach to uniformity was noticed in them all. The Committee had evidently not needlessly multiplied terms. Those signs which were not included in all lists were unimportant, with the exception of cavernous respiration, which was wanting in the German. There were no essential points of difference in the nomenclature. The term subcrepitant râles was wanting in all the lists, and was, the speaker thought, superfluous. No variation existed in the definition of palpation sounds, but there were some differences in the definition of the percussion sounds. In the American list it was stated that prolonged expiration may be high or low in pitch; the high pitch indicated consolidation. Râles in the French nomenclature mean either dry or moist sounds; in the English, only moist. The definition of bronchophony and pectoriloquy varies in the different lists.

It was suggested by the speaker that the report be considered a provisional one, and that representatives of other countries be added to the Committee, to report at the next meeting of the Congress.

THE PRESIDENT returned thanks for the report, and expressed his approval of the principles upon which it was drawn up.

The suggestion of Dr. Flint as to the provisional nature of the report was submitted to the meeting and adopted.

Several of the members criticised the report, as regarded some of its features.

DR. FLINT replied that the report was only intended to be a provisional one.

PROFESSOR TOMMASI CRUDELI, of Rome, then read a paper on

MALARIOUS INFECTION IN MAN.

The human organism presents different degrees of resistance to the action of the malarial poison. Sometimes this is of very high degree. It may often be hereditary in nations, appearing to be the effect of natural selection. In our day, however, this happy selection is impossible, at least among civilized races, and has been replaced by specific degeneration of the inhabitants of malarious countries. We may, however, oppose this tendency to degeneration from the effects of the malarial poison by means of a simple and inexpensive prophylactic medication.

The specific ferment of malaria attacks directly the

red blood-corpuscles, and causes necrobiosis as the final result of a series of alterations in the protoplasm of the cells. These changes are characteristic and pathognomonic as a sign of infection.

Dr. A. Goldschmidt, of Lyngby, Denmark, exhibited a chart showing the progress of

MALARIAL EPIDEMICS IN DENMARK.

He related briefly the history of these epidemics and showed their close connection with floods due to irruption of the sea, or to excessive rainfall.

Dr. Kering, of St. Petersburg, presented a communication on

CEREBRO-SPINAL MENINGITIS.

He described the etiology, pathology, and symptoms of the disease. The section on treatment contained no very novel suggestions.

Tuesday, August 12th—Second Day.

The Section was called to order by Dr. Bouchard, of Paris, who occupied the chair.

Professor Ewald, of Berlin, read a paper on the

GENERAL MANAGEMENT OF TUBERCULOSIS AS INFLUENCED BY RECENT INVESTIGATIONS IN EXPERIMENTAL PATHOLOGY.

The author reviewed briefly the subject of the tubercle bacillus, and then showed how the theories of Koch and his followers had influenced the teachings on etiology, diagnosis, prognosis, and treatment.

Dr. J. Grancher, of Paris, then followed with a communication entitled

THE EARLY DIAGNOSIS OF PULMONARY TUBERCULOSIS.

In the pneumonic form of pulmonary tuberculosis, and in that form which begins with hæmoptysis, or with a violent cough, the presence of the tubercle bacillus is an all-sufficient diagnostic sign. But in that more common form, in which the commencement is very insidious and unaccompanied with expectoration or cough, the bacilli cannot be detected. They can only be found after expectoration has begun, and then the diagnosis is certain enough without this additional proof.

The most conclusive sign in this early stage is a slight roughening with lowering of tone of the inspiratory murmur. This inspiratory abnormality is sufficient for a probable diagnosis when it is distinct, permanent, and localized at the apex of the lung, and when the patient is scrofulous or presents an hereditary or other predisposition to tuberculosis. This change in the sub-clavicular inspiratory sound is found more frequently on the left than on the right side. It is true, however, that very slight causes may produce this alteration in the vesicular murmur, a transitory congestion at the menstrual period, for example. Hence it is not well to rely upon it too strongly unless it is permanent, and unless an increased probability is furnished by the general condition of the patient.

Dr. Quinlan, of Dublin, presented a note on the

TREATMENT OF PULMONARY CONSUMPTION.

The Library of the Royal Irish Academy, in Dublin, contains a large number of manuscripts in the Celtic language, treating upon medical subjects. In these, mention is frequently made of the mullein plant as a remedy in pulmonary diseases. And at the present day it is largely employed by the Irish in consumption. The plant is known to botanists as the

VERBASCUM THAPSUS.

The author had made a number of experiments to determine its efficacy, and concluded that it possessed considerable value. It is given in infusion in milk, and the leaves are smoked for the relief of cough.

Dr. R. Shingleton Smith, of Bristol, read a short communication on

IODOFORM IN THE TREATMENT OF PHTHISIS.

The drug had acted well in his hands in reducing temperature, and improving the general condition of the patients.

Dr. Jaccoud, of Paris, concluded the discussion of pulmonary phthisis with a paper on the

TREATMENT OF TUBERCULOSIS AS INFLUENCED BY KOCH'S THEORY.

He maintained that the discovery of the bacillus tuberculosis has been singularly sterile in its effects upon the treatment of phthisis. He also insisted, in regard to prophylaxis, that precautionary measures against infection had been taken long ago. The main point to be held in view was to maintain the health of the upper part of the lung, and so to render it proof against infection. The good effects of high altitudes were due to the fresh air and means of exercise. He had himself pointed out the freedom of such localities from micro-organisms in the air. As to Koch's theory, he was of the opinion that it had great nosological interest, but that it was of no value in a therapeutic sense. Possibly in the future the discoveries of M. Pasteur may come to be of some prophylactic importance.

At the afternoon session Professor Austin Flint occupied the chair.

Dr. W. B. Hadden, of London, read a paper on

MYXŒDEMA AND ITS PATHOLOGY.

This is a disease characterized by a general swollen condition of the body resembling dropsy, except that the parts do not pit on pressure. The general expression of the sufferers is placid and inert—in a word, cretinoid. The skin is dry and harsh, perspiration and sebaceous secretion are absent, and the hair, nails, and teeth share in the general malnutrition. There is wasting of the thyroid gland. The temperature is almost constantly subnormal. The speech is slow, thick, and nasal, and the tongue seems too large for the mouth. An indisposition to all mental and bodily activity is one of the most striking features of the disease. The appetite is poor, deglutition is often difficult, and defecation seems to be hindered by a swollen condition of the rectal mucous membrane.

The disease usually attacks adult women, but it may possibly commence during adolescence. It occurs among rich and poor, and climate and race seem to be without influence.

As to morbid anatomy, there is always a diminution in size of the thyroid gland. According to Ord there is solid œdema of the connective tissues, and a great increase in the amount of mucin; hence the name myxœdema. The author believed that the disease is dependent upon changes in the sympathetic nervous system, and he thought it not unlikely that the thyroid is in some relation with the peripheral sympathetic nerve-fibres. This view, he stated, had recently been borne out by post-mortem evidence.

An improvement has occasionally followed the employment of jaborandi.

Professor Brandes, of Copenhagen, then exhibited

A LIVING SPECIMEN OF MYXŒDEMA.

The woman was forty years old and had suffered from the disease for eleven years. The symptoms began with loss of power in the right hand, followed by a melancholy sluggishness of the intellect. The urine had contained but very little albumen.

Sir William Gull said he had published a paper on

CRETINISM IN ADULTS

eleven years ago. This was what is now called myxœdema, but it is not a new disease. It is merely sporadic

cretinism in the adult. Cretinism comes on at any period of life and in any degree, and is often not recognized by the physician.

Dr. Ord, he continued, looking on it as a special disease, looked for a special pathology and termed it myxœdema. The myxœdema in such cases is accidental, not the essence of the disease.

Dr. Mahomed said that Sir W. Gull's earliest observations were remarkably confirmed by our latest knowledge of the disease. All the truth about it, however, was not contained in his remarks. Is the disease a permanent one? He thought it was not necessarily. In some cases it is not general, but confined to some local portions of the body. The disease is a perverted nutrition, not necessarily a permanent perversion.

Many cases have been seen to improve under treatment; one case, under the speaker's own observation, dated from two years back. At first there was no albumen, but later the urine was highly albuminous. The patient disappeared for a time, but a few weeks ago applied for admission. At this time the myxœdema and cretinism had quite disappeared. There was no albumen in the urine, but the patient had ascites and general dropsy. The abdomen was tapped, the patient had epileptiform convulsions and died in three days. At the autopsy there was found a thickening of the capsule of the liver; the kidneys were not granular, and there was no myxœdema of the tissues. The disease had evidently disappeared.

He related a second case, which was under the care of Dr. Goodhart some years ago. The patient came into the hospital lately and died there. She was a withered old woman, but presented no trace of myxœdema. The occurrence of mucin in the tissues, he continued, is probably accidental, as Sir W. Gull says, and is the result merely of œdema, as is often seen in œdema from venous obstruction, in which he had often seen similar brawny swelling. It is safe to say in such a disease there is an affection of the nervous system, but this is probably secondary, not primary. The sympathetic system is probably at fault. He confessed he would not quite like to see the explanation in simple cretinism or in disease of the thyroid gland.

A number of the members then participated in a

DISCUSSION ON TUBERCULOSIS.

Among those who spoke were Professors Paul Guttman, of Berlin, A. Pribram, of Prague, and Dr. Croig, of Brussels. The discussion elicited nothing of any special interest.

The following day, Wednesday, August 13th, was devoted to excursions around Copenhagen, and there was consequently no work in the Sections.

THURSDAY, AUGUST 14TH—FOURTH DAY.

Dr. Biermer, of Breslau, presided at the opening session.

The first paper of the day was read by Professor R. Lépine, of Lyons, and was entitled

CLINICAL OBSERVATIONS ON SOME AUTO-INTOXICATIONS.

The different forms of self-poisoning were grouped by the author under the following heads:

1. Auto-intoxication in diabetics, diabetic coma. Allied to this is the form of poisoning sometimes seen in patients suffering from cancer of the stomach.

2. Auto-intoxication of intestinal origin, intestinal septicæmia. This may occur in strangulated hernia, artificial anus, and in various other intestinal lesions, even where there is no obstruction in the gut.

3. Auto-intoxication of bronchial or vesical origin.

4. Auto-intoxication as the morbid element in acute infectious diseases.

The author then spoke briefly of the diagnosis of these different forms of self-poisoning, and set down the rules for their hygienic and therapeutical management.

The views advanced in the paper were criticised by Professor Stadelmann, of Königsberg, and Edefsin, of Kiel.

A communication was then presented by Professor Liebermeister, of Tübingen, entitled the

ANTIPYRETIC TREATMENT OF ACUTE INFECTIOUS DISEASES.

He said that a great danger in fevers arose from the elevated temperature, and it was the problem for the physician to reduce the pyrexia. The basis of antipyretic treatment is the direct withdrawal of heat by cooling baths. In many cases, however, the exhibition of antipyretic drugs is a useful auxiliary.

Professor Bouchard, of Paris, followed with a paper on the

ANTISEPTIC TREATMENT OF INFECTIOUS DISEASES.

The paper was a presentment of the views of Dr. Warfvinge, of Stockholm. He showed that the high temperature is not the essence of the disease, but is only an important symptom, and consequently is not the main point for attack in treatment. It is impossible to obtain a reduction of temperature by cold baths except by repeating them with great frequency. It is more rational to employ internal remedies, which at the same time reduce the temperature and repress the production of heat. It is most probable that all infectious diseases are due to the presence of inferior organisms within the economy. It is therefore more rational to attack them as the cause, rather than the fever as a symptom. But it is known that the so-called antipyretics are also among our most powerful antiseptics, and this probably explains their mode of action. Although any possible concentration of a drug within the body is too weak to kill these organisms, it is probably strong enough to so paralyze them that they become incapable of exerting their deleterious effects. The system thus gains time to recuperate, and finally becomes strong enough to expel the already weakened micro-organisms.

The writer then gave a résumé of Dr. Warfvinge's experiments with various antiseptics in fevers. He regarded phenic acid in the treatment of typhoid fever with especial favor. Alum he had found of great service in the treatment of pertussis.

At the afternoon session, Professor Lépine, of Lyons, occupied the chair.

The greater part of the session was occupied by a

DISCUSSION ON COLD BATHS IN FEVERS,

as advocated in Professor Liebermeister's paper. Some of the speakers animadverted very strongly on the dangers of this method, and expressed a decided preference for the employment of internal antipyretics.

Dr. Pribram, of Prague, spoke of the value of

ANTIPYRIN.

This was a new remedy, but the results of a number of experiments by different observers would seem to show that we possess in this artificially formed substance, an antipyretic of undoubted worth.

Professor Liebermeister replied briefly to the criticisms of the cold water treatment, and defended with some spirit its claims as the best method for reducing temperature in fevers.

Dr. Brondet, of Paris, read a paper on the

TREATMENT OF INTESTINAL OBSTRUCTIONS BY ELECTRICITY.

He detailed the methods employed by him, and illustrated his remarks by a number of cases happily relieved by this treatment.

FRIDAY, AUGUST 15TH—FIFTH DAY.

DR. PRIBRAM, of Prague, was in the chair.

PROFESSOR ROSENSTEIN, of Leyden, presented a paper on

MALARIOUS INFECTION IN MAN.

This was followed by an interesting paper by PROFESSOR WITH, of Copenhagen, on

PERITONITIS RESULTING FROM DISEASES OF THE VERMIFORM APPENDIX.

The author said that inflammation of the peritoneum in the right iliac fossa, known by the name of perityphlitis, originates most frequently from ulceration and perforation of the appendix vermiformis. Peritonitis of such an origin is called appendicular peritonitis. It presents itself under three usually distinct forms or stages, to wit, adhesive, local, and general appendicular peritonitis. The first occurs prior to perforation, and the last subsequent to this accident.

As regards treatment, the primary indication is to prevent, as far as possible, all movements of the intestine. With this object in view, it is necessary to give sufficiently large doses of opium or morphine, and also to abstain from the use of laxatives or enemata. The bowels must be kept confined for many days, sometimes as many as twenty-four. If this treatment be pursued, the necessity for surgical intervention will be greatly restricted.

PROFESSOR AUSTIN FLINT, of New York, desired to refer to a point in the diagnosis of perforation of the intestine, viz.,

THE PERSISTENCE OF THE HEPATIC DULNESS ON PERCUSSION,

as a proof that perforation has not taken place. A very small quantity of air in the peritoneal cavity sufficed to abolish hepatic dulness. This might be proved by injecting air through a trocar in the dead subject. A tympanitic resonance over the whole hepatic region was not proof, however, that perforation had taken place, for when the colon is distended, a tympanitic resonance often extends up to the base of the lung. Another point as to the

TREATMENT WITH OPIUM,

and allowing the bowels to remain constipated for a long time, unless they acted spontaneously. This was long ago introduced and practised in New York by Dr. Alonzo Clark, who ascertained that patients could tolerate an enormous amount of this drug. The dose should be gradually increased so as to avoid a toxical degree of narcotism. The rationale of the treatment was complete arrest of peristaltic action, to "put the bowels in splints." Although cathartics or laxatives were dangerous, the rectum might sometimes be emptied by a simple enema, which did not excite the intestine above a peristaltic action.

The paper was further discussed by DRS. EWALD, of Berlin, and MAHOMED, of London.

DR. J. GRANCHER, of Paris, followed with a communication on

SUBACUTE PNEUMONIA.

Subacute inflammation of the lung, so-called splenopneumonia, has no well-defined position in pathological classification. It is confounded now with pulmonary congestion, and again with the pleurisy which often accompanies it as a complication. It differs, however, from acute congestion and passive stasis as much as from acute pneumonia and pleurisy. More nearly allied to broncho-pneumonia, it is yet easily distinguished from it by its localization in one lung, its fixedness, as well as the general character of its clinical features. The mode of origin, the pain in the side, dyspnœa, fever, and dry cough are symptoms which resemble more or less those of pleurisy of medium intensity. But the dyspnœa is more intense and the fever more active and showing greater oscillations. The general condition is more grave than it is in pleurisy. Finally, there is often albumen in the urine. The disease lasts about five or six weeks.

The physical signs over the seat of disease are dulness, absence or diminution of vocal resonance, a soft souffle, broncho-ægophony, and some crepitant râles on inspiration. The signs in the neighborhood of the pulmonary lesion are: below the point and to the left, the preservation of Traube's space; on the right, the persistence of the liver in its physiological position. Above this point, in the sub-clavicular and scapular regions, there is a noticeable enfeeblement of the inspiratory murmur, with tympanism and a permanent or transitory exaggeration of the vocal vibrations. The opposite lung is healthy.

In subacute pneumonia, pure and simple, puncture of the chest-walls with the needle of the hypodermic syringe gives exit only to air and blood. This sign is not, however, always of practical value, as there is often a more or less extensive pleuritic effusion.

On Friday morning, from 10 to 12 o'clock, PROFESSOR TOMMASI CRUDELI gave a demonstration at the School of Technology of microscopic specimens showing the

CHANGES IN THE RED BLOOD-CORPUSCLES IN MALARIA

in the human subject. In each preparation the healthy corpuscles were unstained, but in various parts of the field could be seen other corpuscles containing one or more small colored particles. These particles, he thought, were probably the germs of a bacillus.

SATURDAY, AUGUST 16TH—SIXTH DAY.

There was but one session this day. The principal paper was by PROFESSOR GRAINGER STEWART, of Edinburgh, on the

INFLUENCE OF ACUTE INFECTIOUS DISEASES UPON THE KIDNEYS AND THEIR FUNCTIONS.

The author said that acute infectious diseases were now believed to be due to the introduction into the system of poisonous matters which are capable, under favorable circumstances, of reproducing themselves. These diseases influence the kidneys in two ways: by producing organic, and hence grave and permanent, or functional changes. In considering the

ORGANIC CHANGES

he first described the anatomical alterations. The tubules might be normal in appearance, but were more usually the seat of lesions varying from a slight cloudy swelling of the epithelium to the most pronounced inflammation, with fatty degeneration and breaking down of the cells. In some cases the tubules contained numerous parasitic organisms. In the Malpighian corpuscles the vascular tufts were compressed by swelling of surrounding parts. In some cases there was marked proliferation of the fibrous tissue of the stroma. The next question was:

WHAT IS THE RELATION OF GERMS TO THESE CHANGES?

It is certain that micro-organisms may be found in great numbers in the kidneys in certain of the acute infectious diseases, yet the author himself was convinced, from examinations that he had made in conjunction with Dr. Stacey Wilson, that fatal diphtheria with albuminuria was not necessarily attended with the presence of organisms in the kidney. He was also convinced that well-marked scarlatinal nephritis might run its course without any organisms being present. It seems most probable that a poisonous substance is developed in the course of the disease by which the kidney is irritated.

The third question was:

DO THE INFECTIOUS PROCESSES DIFFER CLINICALLY FROM ORDINARY NON-INFECTIOUS RENAL INFLAMMATION?

The ordinary symptoms are the same, but, strange to say, there appeared to be no room for doubt that virulent organisms were often present in the urine of patients suffering from acute infectious diseases. The author was unable to explain the fact, and thought it might lead to a reopening of the question of micro-organisms in the kidneys, and possibly overthrow the opinions just enunciated by him.

He next considered the question of

FUNCTIONAL ALBUMINURIA,

occurring in the course of acute infectious diseases. This might result from slight changes in the renal structures which speedily subsided, and were consequently never the subject of post-mortem examination. In other cases it was the result of high temperature with transudation of albuminous materials through the renal vessels. Lastly, in some cases it might be due to an alteration of the blood serum from chemical causes, by reason of which transudation through the vessels occurred more readily than in health.

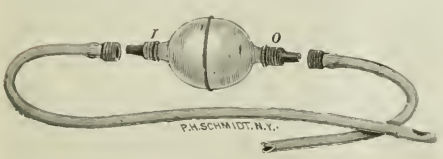
The Section then adjourned at 1 o'clock.

New Instruments.

A SIMPLE STOMACH-PUMP.

By D. H. GOODWILLIE, M.D.,

NEW YORK.



THE accompanying cut represents a simple and efficient pump for the removal of blood and mucus from the stomach, to prevent vomiting, after operations on the nose and mouth, particularly that of staphylorraphy. It can also be readily used in the bladder or rectum. It consists of a heavy rubber ball of two-ounce capacity, having an in-valve (I) and an out-valve (O). To this is attached by a simple hard rubber connection the stomach, bladder, or rectum tube, of flexible rubber, of different sizes for children or adults. The tube at the other end to be placed in the vessel of liquid.

When it is to be used, pass the disconnected stomach tube into the stomach. Fill the connected ball and other tube from the vessel, keep it upright, with the tube downward, connect it to the stomach-tube, and gently force the required quantity of liquid into the stomach. Then disjoint the tubes, reverse the ball, rejoin tubes, and gently pump out. Repeat if necessary.

Its advantages are, that it is simple in structure, has extra large valves, good strength, is always ready, and easily used.

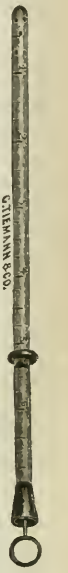
THE RECORD NOT BEATEN AFTER ALL.—Dr. L. A. Rodenstein, of this city, sends a note calling attention to a case reported by him in the *American Journal of Obstetrics*. It was that of a polycystic ovarian tumor weighing one hundred and forty-six pounds. "So," writes our correspondent, "Dr. C. C. Stockard's case, published in THE RECORD of August 16th, is not the largest on record, and New York still holds the champion cup, as far as large tumors are concerned."

A NEW SOFT RUBBER VELVET-EYED TUBE FOR INJECTING OR MEASURING THE UTERUS.

By W. THORNTON PARKER, M.D.,

ACTING ASSISTANT SURGEON, U. S. ARMY.

CONSIDERABLE attention has been given of late to the subject of intra-uterine injections. The necessity for the accurate measurement of the uterus in a great many gynecological cases requires a *safe* instrument. All writers on diseases of women recognize the dangers in the use of the metallic sound.



In too many instances the sound is needlessly used, and often by rough and unskilful operators.

It is impossible to estimate the injury resulting from such meddling.

"The employment of the uterine sound should be resorted to with great care and gentleness, and only when we are likely to gain some information from its use that we cannot otherwise gain. Several instances have been recorded where the point has been made to perforate the wall of the uterus. This accident is most likely to happen when the organ is in a softened state, such as occurs during the fatty degeneration of sub-involution following abortion or parturition, or in the ulcerative stage of cancer. It has been suggested that the point may have passed along a dilated Fallopian tube, but although this may explain some few cases where the point of the sound has been felt beneath the abdominal wall, there is *little doubt* but that in the *majority* of *such cases perforation* of the *uterine wall has actually occurred*."[1]

"*If* the *uterus* be in its *normal position*, and the *sound* be *used* by a *skilful hand*, the operation is not *difficult*. *But* it is *not* the *healthy* uterus which we are generally called upon to explore. If the organ be displaced, the difficulties and dangers attending the employment of the sound are considerable. The facts which may be ascertained by the sound are these: 1, the capacity of the uterus; 2, the existence of growths within it; 3, deviation of the course of its canal; 4, differentiation of displacements from uterine tumors; 5, the mobility of the uterus."[2]

The great importance of these facts with reference to diagnosis is evident, and one would suppose that an instrument revealing so much would be universally employed. Such, however, is not by any means the case. By adepts it is commonly resorted to, but in general practice will be found many, indeed a majority, who do not employ it *from fear of its results*, the difficulty of its introduction, and uncertainty as to its revelations.

"Some remarkable accidents prove the necessity of exerting the utmost care and delicacy of touch in using the sound. The point of the instrument has actually perforated the fundus of the uterus. Two such cases were observed by Schroeder. In both the sound went without force sixteen to seventeen centimetres deep, and its knob was felt through the thin abdominal walls. The most careful and judicious use of the sound is sometimes *attended* and *followed* by *intense pain*. Metritis has occurred, and this even when there was no reason to infer that the wall had been perforated. That *fatal accidents have occurred* from *the use* of *the sound can hardly* be *doubtful*."[3]

It has occurred to me that some improvement is required in our instruments for intra-uterine injection, and also that some gentler if not more precise method might be employed in measuring the uterus than that of the metal sound. The accompanying very simple contrivance has been devised, which may be found useful in the operations for which it is intended.

This uterine injecting and measuring tube is made of pliable rubber somewhat stiffer than the rubber catheter. It corresponds in diameter to the No. 13 Tiemann & Co's American Scale, although it can be used larger or smaller in diameter if desired. It is ten inches long, and fits securely, when needed for injecting purposes, over the nozzle of the common hard rubber uterine syringe. For about six inches it is marked with one-eighth, one-fourth, one-half, and one inch divisions. There is no terminal orifice, but there are twelve "velvet-eyed" apertures to permit the escape of the fluid for injection *obliquely backward*. The tube can be easily and painlessly introduced into the uterus, and by slipping the black hard rubber ring forward against the *os*, the length of the uterine canal can be accurately determined. The tube being flexible, and the orifices "velvet-eyed," the danger from injury to the uterus is reduced to the minimum. The wire provided for use, when used as a *measurer*, will be found sufficiently stiff to make the instrument a very acceptable sound. If this measuring tube can sometimes be substituted for the more dangerous metallic sound, and with equal accuracy, the object of its manufacture will have been accomplished.

FORT UNION, NEW MEX.

A NEW SPRAY PRODUCER.

BY CYRUS EDSON, M.D.,

NEW YORK.

THE instrument represented by the accompanying illustration is a modification of the ordinary nasal application, and has been designed for making medicinal applications to the mucous surfaces of the nares, pharynx, and larynx. It consists of a hard rubber tube, about five inches long, having an oblong bulbous extremity, divided near its proximal end by a thread and screw joint.

To use the instrument the bulb is unscrewed and packed with absorbent cotton or sponge, which is then saturated with the chosen solution. The bulb having been screwed in place, the instrument is attached to a compressed air-receiver and used like a Sass' tube.

The spray is somewhat coarser than that produced by the latter atomizer. A tip is provided for delivering it in any direction.

To the practitioner who is not a throat specialist it commends itself for the following reasons: It is practically indestructible; it is not liable to become clogged; it does not require specially constructed bottles for the medicinal solutions. It is an excellent powder blower.

GLASS IN PEPSIN PACKAGES.—Dr. S. E. Campbell, of South Bay City, Mich., sends us a note of warning to physicians who dispense their own pepsin. A medical student suffering from gastric insufficiency (we have never met with that trouble in medical students, by the way) purchased a pound package of saccharated pepsin made by a New York firm. In taking his dose he noticed occasionally something hard in his mouth. Finally he sifted the pepsin and found a number of bits of broken test-tube. We presume that the mixture is not a common one, but a word of warning is not out of place.

Correspondence.

INTERNATIONAL MEDICAL CONGRESS NOTES.

(From our Own Correspondent.)

COPENHAGEN, DENMARK, August 23, 1884.

THE OPENING ON SUNDAY—THE EXCURSION IN THE MIDDLE OF THE WEEK—PROFESSOR LANGE, THE SECRETARY-GENERAL—HOW HE USED HIS OFFICIAL POSITION IN HINDERING THE PRESS IN OBTAINING LEGITIMATE INFORMATION — THE SECRETARIES OF SECTIONS IN THE RÔLE OF OBSTRUCTIONISTS—DIFFICULTIES IN OBTAINING INFORMATION GENERALLY—THE BANQUET IN THE TENT AND THE NOVEL WAY OF RESPONDING TO TOASTS—BRILLIANT RECEPTIONS AND FREE LUNCHES.

IN my previous letter, hastily written before the closing of the mail, I endeavored to give a general idea of the great medical meeting here, but I found on looking over my notes that there are many things which I might have said but for the hurry.

The choosing of Sunday as the day for the opening ceremony was not much in accordance with American or British notions, but I suppose it did not seem *outré* to Continentals. It certainly would not have been done in America or England. The singing of a cantata after the speeches and before the Congress was declared open had a novel but very pleasing effect.

On the whole, those who attended the recent Congress have no reason to complain of the Danes. Judging of them by the Congress week, one cannot but pronounce them a most hospitable nation. Receptions, banquets, excursions followed one another in rapid succession, alternating with the more serious work of the Congress. The idea of giving up a whole day to excursions in the middle of the week was certainly somewhat novel, but the result was most enjoyable.

Professor Lange, the Secretary-General, made a speech at the opening ceremony. He was very nervous, and spoke so low that no one more than a few yards from him could hear a word he said, and altogether made rather a poor impression as an orator. Before leaving Professor Lange I desire to place on record that, in his official capacity of secretary, instead of affording facilities to representatives of the press he either would not or could not give them any assistance, but apparently endeavored to obstruct them. He speaks English fluently, so he cannot plead as an excuse that he did not understand the English-speaking journalists who applied to him. Several of the secretaries of sections also were very loth to communicate what they knew about the proceedings. Some of them excused themselves by saying they had been away part of the time. How a complete set of the transactions will be prepared I am sure I know not.

One of your London contemporaries sent a representative accompanied by a short-hand writer. The former found such insurmountable difficulties in getting information that, finding his short-hand writer practically useless, he told him he might as well go off to Norway, or somewhere else, and take a holiday.

The sections unfortunately did not meet near together, but in three different places, any one of which was roughly speaking a mile from either of the others. As the fourteen sections all met simultaneously, your readers can form some idea of the difficulties of getting information from each.

Passing to more pleasing recollections let me say that the trip to Elsinore, in which nearly all the members of the Congress participated, was most enjoyable. The luncheon in the Kronberg Castle was laid in twenty-two rooms.

Perhaps of all the scenes in connection with the Con-

gress the banquet in the tent on the Custom House Quay will be the longest remembered by those who were present. This was on Thursday afternoon. It began at five o'clock and terminated about half-past eight. To accommodate the immense number present—about two thousand, including visitors—forty-two tables were laid. To wait on the army of guests one hundred and sixty-eight servants were provided, who served the successive courses as the signal was given by ringing a large bell. The *menu* was sumptuous, but most unlike an average London or Parisian dinner. The speeches, too, were given in a most eccentric manner. The guests were not allowed to dine in peace and then enjoy the "feast of reason" and "flow of soul" afterward, but they were interspersed between the courses, sandwiched, in fact, between the viands provided for mere bodily refreshment. They began directly after the soup had been served and partaken of, and from thence onward to the conclusion of the meal either a speech, a song, or music diversified the intervals between the courses. When a speech was being delivered by an eminent member the dinner was forgotten and the assembly vacated their seats *en masse* and rushed to the other end of the immense tent so as not to lose a word. Venerable and distinguished members of the profession were seen running helter-skelter like so many schoolboys. I saw one specimen of the latter genus present by the way—apparently a son of one of the members present. Sir James Paget spoke to him and said, "I am very glad to see you, my boy. We shall all of us remember this occasion to the end of our lives, but you, being the youngest of us, will remember it longer than any of us." Virchow also spoke to him.

Despite the successive interruptions the vast dinner came to an end at last. All then embarked on board the steamers provided and went by way of the canal to the Tivoli Gardens. The banks were lined with spectators, who cheered loudly as the Congress passed. Many boatmen were on the canal and cheered and saluted with their oars as they passed us. Many of them burnt blue and red lights. Rockets and other fireworks were discharged, illuminations were displayed, and the electric light shone brightly from many vessels and houses. At Tivoli about forty thousand people had assembled. The whole formed a never-to-be-forgotten sight. The closing festival on Saturday was also brilliant.

I must not omit to mention that throughout the Congress free lunches were provided for such as chose to partake of them. Free railway passes were also granted from Copenhagen to the frontier.

Despite a few drawbacks, I think I may safely say, in conclusion, that all who took part in the Congress of 1884 will remember with pleasure the courtesies and hospitalities shown them by the Danes in their beautiful capital, Copenhagen.

Muriate of Ammonia.—It increases the secretion of mucus from the alimentary canal, and is supposed to render the blood less plastic and coagulable, without impairing the structure of the corpuscles. Its habitual use causes emaciation, renders all the secretions freer and more abundant, and exerts an alterative and absorbent action, especially on the connective tissues, in hyperplasia and cirrhosis of many organs. It has even exerted some beneficial influence upon fibrous tumors of the uterus, and much more upon chronic engorgement of that organ. Its slow but steady modification of the nutrition of the connective tissues has been seen in chronic enlargements of the liver, spleen, prostate, thyroid, and other enlargements. It cures many cases of gleet and if any internal remedy will relieve strictures of the urethra, this is the one most apt to do it. It cures some cases of neuralgia depending upon thickening of the neurilemma, and is one of the best remedies in fibrous phthisis. If other remedies fail, it should be tried in sclerosis of the cord and brain depending upon thickening and induration of the neuroglia.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 31 to September 6, 1884.

Byrne, Charles C., Major and Surgeon. Relieved from duty in Department of California, and to report in person to the Commanding General, Department of the Platte, for assignment to duty. S. O. 207, A. G. O., September 3, 1884.

Town, F. L., Major and Surgeon. Relieved from duty in Department of the Columbia, and to report in person to the Commanding General, Department of Texas, for assignment to duty. S. O. 207, C. S., A. G. O. Granted leave of absence for twenty-five days. S. O. 127, Department of the Columbia, August 25, 1884.

Havard, Valery, Captain and Assistant Surgeon. Relieved from duty in Department of Texas, and to report in person to the Commanding General, Department of the East, for assignment to duty. S. O. 207, C. S., A. G. O.

Hall, William R., Captain and Assistant Surgeon. Relieved from duty in Department of Texas, and to report in person, on October 1, 1884, to the Superintendent General Recruiting Service in New York City, for duty at David's Island, N. Y., relieving Assistant Surgeon M. E. Taylor from duty at that station. S. O. 207, C. S., A. G. O.

Hopkins, William E., First Lieutenant and Assistant Surgeon. The leave of absence granted him in S. O. 67, August 7, 1884, Department of Arizona, is extended one month. S. O. 204, A. G. O., August 30, 1884.

Official List of Changes in the Medical Corps of the U. S. Navy, during the week ending September 6, 1884.

Rixey, P. M., Passed Assistant Surgeon. From special duty at Washington, D. C., September 8th, to the Lancaster, European Squadron.

Oberly, A. S., Surgeon. From the Richmond, August 30th, and wait orders.

Dickson, S. H., Passed Assistant Surgeon. From Arctic Squadron, July 29th. Sick leave August 30, 1884.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 6, 1884:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.

September 6, 1884	0	18	6	2	9	9	0	0

Famous Examples of Nervous Exhaustion.—Much of the world's best work has been done by neurasthenics, says Beard. George Eliot, Darwin, Heine, Spencer, Edwards, Kant, Bacon, Montaigne, Joubert, Rousseau, Schiller, illustrate the possibility of not only living, but of doing original work on a small capital of reserve force.

The American Laryngological Association Viewed from the Outside.—The *Burlington Hawkeye*, in noticing the holding of the sixth annual Congress of the American Laryngological Association, takes occasion to thus enlighten the lay public as to the nature of that body and its functions: "A laryngological association, my dear, is, we take it, an association of larynxes. And a larynx is—well, it is the active principle of your 'Adam's apple;' the larynx lives in your neck, third floor front, between the tongue and the trachea; it has nine cartilages, and looks like an old garden hose gone to seed. And its uses are—well, you know when a little mouse runs across the floor? Well, your larynx is what you use then. 'Climb on the table with it?' Great Scotland, no! Who ever heard of climbing up on a table with your larynx? No, girl; you 'holler' with it. That's what you do with it, and no foolishness about it, either. And this American Laryngological Congress, we suppose, is organized to devise some means whereby to supply a new India-rubber, copper-lined larynx for the star-eyed goddess of reform, she having shrieked hers wide open and split it down the back when Morrison fell."

Chloroform in the Treatment of Tape-worm.—Dr. Henry K. Gardiner, of Providence, R. I., writes: "In Vol. 26, No. 4, Medical Record, Dr. J. G. Brooks reports several cases of tape-worm treated by chloroform, and claims excellent results. Having a case which I had previously treated unsuccessfully, I prescribed the following: ℞. Chloroform, ʒ j.; muc. acaciæ, ʒ iij. M. Sig. All to be taken at once after twenty-four hours' fasting, to be followed in thirty minutes by two drops of croton oil mixed with bread crumbs. It produced complete anæsthesia of the patient in two or three minutes, the effects lasting ten minutes; and for some hours after headache and drunkenness were complained of. The ol. tiglii was given an hour after taking the chloroform, and tape-worm expelled entire in about twenty minutes. I should like to hear of other cases where the action of chloroform was similar."

Internal Use of Nitrite of Amyl.—Dr. J. F. Dixon writes to the *British Medical Journal:* "There is only slight mention in the text-books, and scarcely any reference in periodical literature to the internal use of nitrite of amyl. Its very temporary and ephemeral action when inhaled has plainly caused therapeutists to cast about for an agent which produces more continuous results. I believe that in nitrite of amyl given internally we have a drug which meets all the requirements of cases in which it is important to lower the arterial tension; and further, that it is free from the uncertainty of action and the sometimes dangerous results of nitroglycerine and nitrite of sodium, which have been employed apparently as substitutes for it. I have employed it thus in cases of anginous attacks of a very severe character. One, complicated with very loud mitral systolic murmur and nightly angina; the second with an aortic systolic murmur, and the third with irritable action, but no apparent organic lesion. I may say, without going into particulars, for this purports to be the merest sketch, that in all these cases the relief was of a marked and abiding character. The dose I employed was 2½ minims three times in twenty-four hours—of course, seeing the case twice daily until the action of the drug was established, when a dose each night was sufficient.

Dissensions in the Baltimore Medical College.—For some months past, says the *Maryland Medical Journal*, rumors have been afloat of inharmonious proceedings in the Faculty of the Baltimore Medical College. We now learn that these have gone so far as to result in a division, and there are now two faculties, each claiming to be the rightful Baltimore Medical College. One faction, headed by Dr. Bryd, has secured a building in the eastern section of the city, while the Munroe party is entrenched in one in the northern part of the city. Each has issued a catalogue, and matters are rapidly coming to a crisis. An early suit, to determine who is legally entitled to the rights and franchises conferred by the charter, is foreshadowed.

Cerebral Congestion during Mental Work.—Mr. Beecher once told the late Dr. Beard that after preaching his head and neck are sometimes so surcharged with blood that a large seventeen-inch collar is very tight for him, but in an hour or two the circulation is restored and no harm results.

Quinine Diminishes Sweating after work upon a hot summer day, according to Liebermeister and Kerner.

That Florida Climate.—*Mens conscia recti* is not much disturbed by slander. We continue to receive earnest protests from Gainesville physicians regarding the views on the climate of Florida promulgated by Dr. Boyland. We had every reason to believe that the views expressed were essentially correct, nor do we think that in a calm discussion it would be found that he differed very much from the local physicians. Florida is an excellent place for many cases of incipient phthisis; but it does not benefit all cases. On the other hand, the climate is often of the greatest benefit in nervous, catarrhal, and rheumatic troubles. This is the substance of the matter. *Per contra*, Florida is not always Paradise. It has no cataracts, no rushing streams, and its most admiring residents refer to mounds of earth sixty feet high as hills. It will be difficult to prove, therefore, that its topography is admirably adapted for drainage. However, we have not the slightest desire to do injustice to the State or any part of it. We therefore publish a portion of an account by Dr. N. D. Phillips, of the topography of Gainesville, and with this we must close the discussion. Dr. Phillips says: "There is a never-failing stream of limpid water running through the town from north to south, which stream separates Gainesville from East Gainesville. From the point where said stream enters the northern boundary, to where it crosses the southern boundary of the town, there is a fall of forty-seven feet. The bed of this stream, due east of the public square, is thirty-five feet below the general level of the town on either side, and grows deeper as it meanders among the hills on its way to Alachua Lake, *eighty-six* feet below the centre of Gainesville. Due west of the public square about four hundred yards, is the head of a deep ravine, also running south, with precipitous banks, fed by never-failing springs of pure water. The fall in the bed of this stream is greater than in that of the stream just mentioned." Another stream is described arising near the town and emptying into Canapaha Lake. "Alachua and Canapaha Lakes both have subterranean outlets, which outlets are sufficient, although the lakes are fed by numerous springs and bold streams, to prevent them from overflowing their banks, even in the wettest seasons." With reference to the "stagnant water of which the doctor speaks, it is only necessary to state that *tons* of the finest fish are caught from Alachua Lake annually and shipped to cities north of this, and a great deal of money realized from the business." We are told that since the leading hotel was built, in 1876, only eight deaths have occurred within its walls. Gainesville is 213 feet above the St. John's River at Palatka, and 86 feet above Alachua Lake.

The Forceps in Breech Presentations.—Dr. J. H. Fruitnight, of this city, writes: "In connection with the short notice of 'The Forceps in Breech Presentations,' on page 192 of your valuable journal of the issue of August 16th, let me direct your attention to a paper written by me on that subject and published so long ago as July, 1877, in the *Virginia Medical Monthly*, page 246, and which, so far as I know, is one of the first articles advocating such use of forceps."

The Medical Record

A Weekly Journal of Medicine and Surgery

Vol. 26, No. 12 NEW YORK, SEPTEMBER 20, 1884 Whole No. 724

Original Articles.

THE RECTUM CONSIDERED AS A RECEPTACLE FOR THE GRADUAL ACCUMULATION AND RETENTION OF THE EXCREMENTAL MATTER.

By WILLIAM BODENHAMER, A.M., M.D.,

NEW YORK.

OWING to the recent attempts of some authors to sustain with new arguments the theory of Mr. O'Beirne, that "the rectum is not a receptacle for the fecal matter, neither was it ever so designed," I feel disposed to offer some arguments in favor of upholding the opposite theory. The late talented Dr. Bushe, many years ago, made a very able argument against the theory of Mr. O'Beirne.[1] It will be perceived, however, that the line of my argument differs materially in several respects from that of Dr. Bushe.

As a preliminary to the investigation of this subject, it is necessary to consider briefly the form, position, direction, dimension, and structure of the rectum, as well as the effect of that structure upon the accumulation of fecal matter in its cavity.

The form of the rectum at its commencement, like that of the sigmoid flexure of the colon, with which it is continuous, is cylindrical, and it maintains this form throughout a considerable portion of its extent; but toward its inferior extremity it becomes large and saccated, forming a terminal pouch, which is dilated from before backward and the mouth of which is closed by the internal sphincter muscle, like a purse. This dilatation, or ampulla, in consequence of the peculiar organization of the parts, is capable of acquiring great size, and in some instances of long-continued retention of fæces it has been found to occupy a very large portion of the cavity of the pelvis.

The structure of the rectum, like that of other hollow viscera of the abdomen, is composed of three regular tunics—a *scrous* or *peritoneal*, a *muscular*, and a *mucous*—which are intimately blended and united to each other by cellular tissue. This connective tissue has been distinguished by some anatomists as an additional coat of the rectum, thus making this organ to consist of four tunics, instead of three, and which tissue they have severally denominated *cellular*, *submucous*, and *nervous*. Be this, however, as it may, it nevertheless is most certainly the connective tissue between the peritoneal and muscular, and between this last and the mucous coat, and may be regarded as constituting the framework of the rectum.

As regards the structure of the rectum, its several coats are gifted with peculiar functions in health, and when under the influence of disease each is subjected to peculiar affections. The muscular coat of the rectum especially possesses great interest, for in this coat resides its contractile power, and to this coat is it indebted for its properties, both as a retentive and as an expulsive organ. The muscular coat is composed of longitudinal and of circular fibres, the disposition or distribution of which merits the careful study of the physiologist. The peculiar arrangement of the longitudinal and circular fibres of the rectum, which differs essentially from that of any other portion of the intestinal canal, has furnished this organ with the power, to a certain extent, of retaining and controlling its contents. The longitudinal fibres are much larger and stronger in the superior portion of the rectum, especially anteriorly and posteriorly, and they become smaller and weaker as they approach the internal sphincter ani. By this change or alteration in the arrangement of these fibres the rectum is enabled, in its inferior portion or pouch, to retain a larger quantity of fecal matter. The circular fibres, on the contrary, are smaller, fewer in number, and more feeble in the superior portion of the rectum where they are less needed and where the action of the abdominal muscles is alone sufficient to propel the contents of this intestine downward. As the circular fibres, however, approach the inferior portion of the rectum, they are more numerous and strong where they are most needed, and are finally blended and constitute the internal sphincter ani. The force exerted by the abdominal muscles in the act of defecation is chiefly expended upon the superior part of the rectum, where the antagonists, the circular fibres, are weakest, and it is exactly in the same ratio in which this force diminishes in the inferior portion of the rectum that the contractile power of the circular fibres in this situation increases. These are facts which cannot be controverted and must not be ignored in the consideration of this subject.

The mucous coat of the rectum, from its peculiar structure, is well adapted for the passage over it of extraneous bodies. It is studded with numerous mucous glands or follicles, from which are derived the mucilaginous fluid which so abundantly lubricates its interior surface, so as to facilitate the passage of the fæces and at the same time to protect itself from mechanical violence. Without this secretion of mucous, or some such lubricating substance, it would be almost impossible for the fæces to be expelled.

The rectum, therefore, being composed of membranous and muscular tissue, is by the first well fitted both to yield and to expand to a gradual and gentle distending force, so as to form a perfect recipient reservoir for fecal matter; while the contractile power of the latter is well fitted to obliterate the cavity of the organ and forcibly eject its contents. This musculo-membranous viscus, then, demands attention, not only as to its structure, but also as regards its situation, form, direction, relations, and connections. The form and direction of the rectum, as well as the structure of its several coats, and its peculiar muscular equipment as a receptive, retentive, and expulsive organ, display a most admirable provision of nature to enable it to perform its numerous offices; indeed, its entire anatomical arrangement evinces a design far beyond human ingenuity.

The utility of the direction of the rectum will at once appear evident when we take into consideration that had this organ been *straight*, as its name implies, we should have been constantly subjected to the unpleasant annoyance, especially when in the erect posture, of a disposition to empty it; its peculiar direction and formation, however, happily protect us against this; and, furthermore, the pouch located at its inferior extremity, allowing a large accumulation of fecal matter to collect, gives sufficient time to the absorbents of the part to take up any nutritive particles that might still remain in the fecal mass. Precisely the same kind of ampulla or en-

[1] A Treatise on the Malformations, Injuries, and Diseases of the Rectum and Anus, p. 23 et seq. 8vo. New York, 1837.

largement obtains in all canals of this character, at such parts of them as have normal contractions below them. In this instance the anal sphincters are the contractors or constrictors and form the impediment to the further progress of the fecal matter for the time being.

I would further remark, with regard to the pouch of the rectum, that Mr. Colles says, that "it is much more evident in adults than in children; however, it will be found in children, except in those of one or two years."[1] Some years ago I examined, *post mortem*, the rectum in several children, their ages varying from six to eighteen months, and in each case I found the rectum of nearly the same diameter throughout its entire length. No dilatation could be observed toward its inferior extremity in any one of these subjects. This pouch evidently does not exist in early infancy, but is subsequently gradually developed, and is doubtless the result of distention, caused finally by the retention and accumulation of the fæces. This begins to take place as the act of defecation comes under the influence of the will; for then it is that the dejections become much less frequent, the fæces increase both in quantity and in consistency, and are suffered to accumulate for a length of time, or until they provoke by their presence, perhaps, the expulsive movement. In early life defecation is chiefly reflex, but it gradually becomes voluntary by habit. In children the fecal dejections take place more frequently than in adults, being usually in proportion to the number of meals. This frequency is doubtless owing to the digestion of children being much more rapid, the intestinal secretions more profuse, the fæces much more fluid, and the sensibility of the alimentary canal much greater. It may also in a great degree depend upon the fact that in childhood the rectum, as before observed, is wholly uninfluenced by the will.

To the rectum, then, of the adult, and especially to its capacious pouch, belongs the office of reception, accumulation, and retention of the fecal matter; while to the anal sphincters, like sentinels, belongs the office of opposing its exit for the time being, and finally of giving permission and of aiding in its expulsion. The rectum, therefore, may with great propriety be denominated the *terminal depôt* of the alimentary canal. Indeed, it is the natural depository of the excrementitious matter just previous to its final exit from the body, except the parts are under the influence of certain diseases, such as dysentery, diarrhœa, etc., when the fæces will not be tolerated in the organ for a moment, but will be expelled as soon as the smallest portion presents itself in it.

It must now be observed, however, that the very able and distinguished physiologist, Mr. O'Beirne, of Dublin, in 1833, as is well known, positively denied that the rectum was a depôt or receptacle for the temporary lodgment of the fæces. He maintained that the sigmoid flexure of the colon was the chief receptacle for the fecal matter while accumulating in quantity sufficient to furnish a proper stool; that in health the pouch of the rectum was always empty of fæces, except immediately before an evacuation; and that the upper part of the rectum intervening between the colon and rectal pouch was not only always empty but firmly contracted by the circular muscular fibres.[2]

Now, according to Mr. O'Beirne, the sigmoid flexure of the colon is the chief depôt for the deposit and retention of the alvine excretions, while the rectum is the mere avenue for the transmission of such, or the mere faucet or funnel through which such are rapidly passed out of the body when called into requisition by the sigmoid flexure. Hence there is no necessity, according to Mr. O'Beirne, for the rectal pouch, nor for the anal sphincters below it, which guard it, inasmuch as his colonic pouch or receptacle is guarded by the superior portion of the rectum, which he says is always firmly contracted and acts as a sphincter, and consequently that the power of retaining and controlling the fecal discharge does not depend upon the anal sphincters.

I, however, hold that the colon and rectum are one continuous canal, and their junction is not provided with a sphincter muscle, such as are the anal sphincters. Indeed, Mr. O'Beirne, feeling the absolute necessity of a recto-colonic sphincter to protect his theory and his colonic pouch, endeavors to prove that the whole of the superior portion of the rectum acts in the capacity of such a sphincter muscle. I, on the contrary, however, positively maintain that the superior portion of the rectum is not any more firmly contracted than any other portion of the intestinal canal not supplied with a sphincter or sphincters, as any expert can at once verify by the proper exploration. It is true the fæces are retarded, and consequently detained longer in passing through the coiled portion of the colon, but this detention there is not owing to any sphincter or sphincters, but is obviously owing to the peculiar form, direction, and position of the sigmoid flexure. It may be admitted that the fæces in the coiled portion of the colon, as in the cæcum, are for obvious reasons detained longer in passing these points than they are in passing other parts of the colon, but this fact alone does by no means constitute these portions of the colon reservoirs for the accumulation of the fæces, as some authors claim, to the exclusion of the rectum as such.

With regard to the very plausible and ingenious theory, so ably presented by Mr. O'Beirne, I respectfully beg leave to differ from it in several respects; for instance, instead of the healthy rectum being always empty between the periods of defecation, as he contends, I am of opinion that it is never entirely so. I hold that even immediately after a natural evacuation of the rectum there is still more or less consistent excrement left in the superior portion of it; indeed, it is more in the character of a displacement merely of the fecal matter of the inferior portion of the rectum, in the ordinary calls of nature in healthy persons, than by a complete evacuation of the whole contents of the organ; for it must be observed that besides the contractile power of this part of the rectum itself the *vis à tergo* of the consistent natural excrement also powerfully aids in effecting a dislodgment or stool. When the rectum is completely emptied by an active cathartic, or a stimulating enema, or as in some diseases, such as dysentery, diarrhœa, the *vis à tergo* is for a time absent, and in a person of good health it requires from two to three days to re-establish it, by the rectum becoming moderately repleted again and so making provision for this part of the natural mechanism by which the consistent fecal matter is ordinarily discharged. The rectum, then, which was designed by nature to serve the place of a reservoir, is never entirely empty when in its normal and healthy state, but always contains some fecal matter in some portion of it, and it is the inferior portion only that is generally evacuated when naturally called to perform this act.

In the exercise of my profession, during a practice of many years, I have examined the rectum in numerous instances, some with special reference to this very question, and I have scarcely ever failed to discover more or less fecal matter in some part of the organ. If the rectum is examined twenty-four hours after an evacuation, the fecal accumulation during that period will generally be found lodged a little beyond the superior margin of the internal sphincter, about four inches above the verge of the anus. With this intention I have examined the rectum in the same individual as often as two or three times in the twenty hours; and for this purpose I use a bivalve speculum ani, introduce it fairly above the internal sphincter, open it sufficiently, and then, through the open blades of this instrument, pass up a No. 2 or 3 English rectal bougie to the superior end of the rectum and withdraw it, and if it has come in contact with fecal matter some of it will adhere to the bougie and can be plainly perceived. In some instances I have found that

[1] A Treatise on Surgical Anatomy, p. 137. 8vo. Philadelphia, 1831.
[2] New Views of the Process of Defecation, p. 3 et seq. 8vo. Dublin, 1833.

the bougie could scarcely be pushed up through the column of solid excrement, which had evidently been lodged in the rectum for many hours. This condition of the solid excrement found in the rectum I have observed to be more common in females than in males. This, however, is said not to be the experience of gynecologists generally, who now, more than ever before, very properly make use of the rectum for diagnostic purposes. But I by no means agree with the author, who says that "gynecologists by their daily examinations in the vagina are quite familiar with the fact that the *rectums*, even of women of torpid habits, are comparatively seldom found loaded with fæces, but empty and flattened between the vagina and the sacrum." I have found that if the examination of the rectum be made just before the usual daily evacuation the fecal mass may often be detected, even by the finger, in ano.

In the dead body I have never found the rectum to be entirely empty, and it may be observed that in anatomical examinations healthy excrement is just as often found in the rectum as in the sigmoid flexure of the colon; indeed, it is sometimes found collected in the caput coli, which has been considered by some as a fecal receptacle, and sometimes found at an intermediate point. This, it appears to me, must be the experience of every one who has had frequent opportunities of examining these organs in the cadaver.

Mr. O'Beirne, in accordance with his theory, has been compelled to assume as probable phenomena which do not admit of positive or demonstrative proof; for example, his conception of the manner in which the fæces are unloaded from or emptied out of the sigmoid flexure into the rectum is, in my opinion, purely hypothetical. I therefore believe that some of his views on this subject are theoretically wrong. I wish particularly to mention here that the healthy fæces do not pass out of the coiled portion of the colon into the rectum continuously, for they, like in other portions of the intestines, are not perpetually in motion, but their movement is intermittent. They neither pass out of the sigmoid flexure at once in bulk sufficient for one ordinary stool, the result of one day's accumulation, as Mr. O'Beirne declares, but pass into the rectum at intervals in small portions, each portion being the fecal residue of but one meal of the solid ingesta of the stomach. As each successive portion is received in the superior part of the rectum, the former one is propelled forward by the impulse given it from behind, assisted by the contractile or vermicular power of the part itself, until it eventually arrives at the inferior part of the rectum, where it and the portions that follow in the same manner slowly accumulate, assume shape and figure, and gradually and gently distend the organ. As a general rule the excrementitial residue of one day's aliment taken into the stomach and amassed in the rectum is considered sufficient to provoke the expulsory movement.

Mr. O'Beirne being continually confronted by the fact that between the periods of defecation fæces were found in the rectum, which he had declared to be always empty, was compelled to notice this, to him, singular circumstance, and to account for it. This he does by attributing it entirely to morbid phenomena, and admitting that by such even the rectum itself may become the final reservoir of the fæces in place of the sigmoid flexure. He says this result is brought about when the whole of the rectum, together with the sphincters, is rendered paralytic. He is very safe in making this admission, for it is well known that injuries of the brain and spinal marrow may and do result in paralysis, not only of the rectum but sometimes of the coiled portion of the colon, as well as other portions of the intestinal canal—thus converting such portions, for obvious reasons, into reservoirs, or stopping-places for the fæces. In compression of the brain the external sphincter is almost entirely disabled, and in compression of the cord the power of the internal sphincter is also impaired. A morbid condition of the rectum, however, in a modified degree, may be produced by atony of its walls, and perhaps this is what Mr. O'Beirne means by the use of the word *paralytic*, that is, merely debility or want of tone. The rectum, like all other hollow viscera, may be subjected to paralysis from injuries of the brain and spinal marrow, as has already been observed, or to atony from undue distention of its parietes by fecal matter, by gas, or by both, as well as from other causes. But the question here, however, is not what the rectum may become by disease, such as paralysis, spasmodic or organic stricture, atony, etc., but is the rectum naturally and in health a receptacle for fæces? That is the question, for it must be understood in this affair that whatever is said concerning the rectum and its functions or actions, both directly and indirectly, must have reference only to its healthy or normal, and not to its morbid or abnormal condition.

One of the recent and ardent advocates of the theory of Mr. O'Beirne, after first declaring that the sigmoid flexure of the colon is the proper receptacle for the fæces, and that the rectum was never designed for such a purpose, proceeds to account for the puzzling phenomenon of finding fecal accumulations in the rectum between the periods of defecation. He declares that whenever fæces are thus found lodged in the rectum it is entirely owing to atony of the walls of this organ, by which it is incapacitated or indisposed to forward on through it at once, without stoppage, the contents of the sigmoid flexure, hence fæces are permitted to accumulate in it. The atony of the rectum is brought about, says he, by the repeated neglect of the calls of nature, by which the rectum is gradually educated to tolerate that which is really irritating to it, and it is only the educated or atonied rectum that ever contains fæces between the periods of defecation.[1] The argument of this author, like that of Mr. O'Beirne, is that the rectum in its healthy state is always empty between the periods of defecation; and that this being its normal condition it cannot, therefore, be a natural reservoir for fecal accumulation; but by pernicious education, however, which he explains, this very susceptible organ may be taught to tolerate in its natural empty, sensitive, and contracted cavity, the presence and the lodgment of fecal matter; and thus finally become that which was not designed by nature, namely, an artificial depository for excrement. The whole argument of this author is to prove that the rectum can be converted artificially into a fecal receptacle by education, as if that was the question at issue, but not a single argument does he give to prove that the uneducated rectum is not normally such a receptacle. This it behooved him to do first, and afterward to account for the fact of fecal matter being found in the cavity of the rectum.

I maintain that the rectum is naturally the terminal depôt, or last resting-place for the healthy excremental matter previous to its final evacuation from the body, and that it tolerates such there for a certain period without being specially educated to do so, for that is its normal function. This is proved by its anatomical structure, its peculiar nervous endowment, and by the fact that, more or less healthy excrement will always be found in some part of the cavity of a normal and sound rectum. This, indeed, is the rule; the reverse of this is the exception. It is true that, by repeated neglect to respond to the daily calls of nature to empty the sound rectum, constipation, or a morbid condition of its parietes is sooner or later induced, by which its sensibility is blunted and its contractile power more or less diminished, this morbid condition being of course greatly aggravated by the repletion, irritation, and excessive distention which follow; so that the rectum ultimately becomes capable of containing and tolerating a much larger quantity of excrement at any one time than normal, and also of retaining it much longer, too, without the natural admoni-

[1] Philadelphia Medical Times, p. 582, November 18, 1882.

tion to move it. But this morbid state of the rectum, by whatever cause produced, is no evidence whatever that it is not a natural receptacle for excrement, previous to such morbid condition consequent upon artificial training.

The *nisus defæcans*, or sensation for the evacuation of the fæces, takes place in the rectum, where it should, and not in the sigmoid flexure of the colon, as Mr. O'Beirne and his advocates claim. The coiled portion of the colon is not under the influence of the will in its movements, but is entirely governed by the automatic operations of the other portions of the intestines, and which terminate at the inferior portion of the rectum, which portion we know is under the direction and control of a separate and entirely different set of nerves. It is doubtless in this portion of the rectum that the *nisus defæcans* originates, and it is through these nerves that the sensation is communicated. The association which exists between the functions of these different nerves is brought into action periodically, when in health, by the distention of the walls of the rectum arriving at a certain stage. This united action, from various causes, as I have already shown, may be disturbed, or it may not be in equipoise, and artificial means, such as cathartics, enemata, or stimulating applications to the lining membrane of the organ, may be required to reproduce the suspended co-operation.

While some physiologists are of opinion that the uneasy sensation which arrests the attention of the will to the act of defecation resides in the rectum, there are others, however, who believe that it does not take place solely in that organ, but is often seated in the stomach, more frequently in the small intestines, and sometimes only in the imagination. Mr. O'Beirne, as before remarked, is of opinion that it originates in the sigmoid flexure of the colon.[1] My opinion is that this admonition originates in the rectum alone, the natural reservoir, in a normal and healthy condition of all the parts concerned, because no portion of the intestinal canal is supplied as this is with the proper nerves to communicate it. When it is experienced in the stomach, in the small intestines, or anywhere else, except in the rectum, it must be in consequence of disease of the stomach, or of such portion of the intestines, or of the brain or nervous system. As to the cause of this admonition there are various opinions. Some allege that it is induced by the mechanical distention of the parietes of the rectum, the result of accumulated fecal matter, gas, or both, and I am of this opinion; others, that it is produced by the mere contact of the fecal matter, the natural stimulus of the intestines, with the interior surface of the rectum; others, again, that it is caused by the acrimony of the fæces, acquired by their retention in the rectum. The truth, however, is that the cause of this sensation is not positively known, consequently all in relation to it is more or less conjectural. Analogy shows that nature employs a somewhat similar agency in the case of other hollow viscera provided with muscular fibres, as the bladder and the uterus.

Mr. O'Beirne's peculiar neurological views on this subject, his ideas on the peristaltic motion or intestinal action, etc., will be fully considered hereafter in a separate article, on the "Anatomy and Physiology of the Sigmoid Flexure of the Colon."

249 Madison Avenue, New York.

Verges.—Old Dogberry's fellow officer derived his name from the corruption of *verjuice* into verges. Verjuice is *verdjus*, or the juice of any green fruit, such as the acid liquor expressed from wild apples, sour grapes, etc.

Sickness and Morals.—"Every man is a rascal as soon as he is sick," said Dr. Johnson.

ON THE TOLERANCE OF CORROSIVE SUBLIMATE IN SMALL AND FREQUENT DOSES.

By ANDREW H. SMITH, M.D.,

new york.

As preliminary to the more extended use of corrosive sublimate as an anti-zymotic or anti-ferment, it is important to settle the question of the safety or danger of administering it in such quantities as may reasonably be expected to act upon the mass of the blood in such manner as to destroy a poison floating in the circulation.

The dangers to be apprehended are, first, local irritation; second, mercurial poisoning.

The following observations will help to form an estimate of each of these dangers. It may be premised that in no case was the degree of dilution less than one in ten thousand. The first eight observations were at the Presbyterian Hospital during my service, and for the notes I am indebted to the kindness of the house physician, Dr. Charles G. Wagner.

Case I.—Annie C——; Irish; married; forty years of age; admitted April 21, 1884. Disease, phthisis pulmonalis, third stage. Patient had been under observation three weeks when mercurial treatment was begun. Temperature had ranged from 100.5° to 103.5°.

May 10th.—She was given hydrarg. bichlor., gr. $\frac{1}{20}$ every hour for seven hours. Temperature did not rise within a degree as high as on the previous evening.

May 11th.—Bichloride continued (largely diluted), gr. $\frac{1}{20}$ every hour for eight hours. Temperature nearly two degrees lower than on previous night.

May 12th.—Bichloride continued. Temperature in morning was normal. In the evening it rose only to 100°.

Treatment was continued, and the case remained unchanged during next three days. On the fourth, patient had bloody diarrhœa, and the bichloride was stopped. Diarrhœa lasted but one day. Treatment was not resumed.

Case II.—Gertrude M——; Irish; single; domestic; twenty-six years of age; admitted February 17, 1884. Disease, chronic diffuse nephritis with mitral regurgitation. Patient had been under observation three months when hydrarg. bichloride treatment was begun. She had for several weeks been passing a very small amount of urine.

May 17th.—Patient was given hydrarg. bichlor., gr. $\frac{1}{20}$ every two hours during the day (none at night). The immediate effect apparently was to increase the quantity of urine. She continued to take the drug for four days, when she had bloody diarrhœa, but no pain in the gums nor any salivation, the bichloride was suspended and the diarrhœa ceased after six or seven passages. Treatment not resumed.

Case III.—Patrick McK——; Irish; single; driver; forty-seven years of age; admitted May 2, 1884. Disease, tertiary syphilis, pachymeningitis (cephalalgia). Patient was put immediately on hydrarg. bichlor., gr. $\frac{1}{16}$ three times a day, with potassii iodidi, gr. xv. t.i.d.

May 15th.—He was put on hydrarg. bichloride, gr. $\frac{1}{20}$ every hour during the day (not in the night). Treatment continued daily until May 20th, when patient had pain in the jaws, and gums felt sore, no marked salivation. Hydrarg. bichloride stopped; ordered, K_2ClO_3.

Case IV.—Julius J——; American; single; twenty-one years of age; admitted April 26, 1884. Disease, chronic diffuse nephritis. Patient had been under observation in the hospital about three weeks; was passing fifty to sixty ounces urine a day, which contained albumen and casts.

May 18th.—He was put on hydrarg. bichloride, gr. $\frac{1}{20}$ every hour. This was continued eight days, during daytime, with no apparent effect on any of the functions. The amount was then reduced to gr. $\frac{1}{16}$ every two hours, which he continued to tolerate until June 3d, when it was discontinued.

Case V.—John O'N——; Irish; married; aged fifty-five. Admitted March 23, 1884. Disease, chronic diffuse nephritis.

May 15th.—Patient was put on hydrarg. bichlor., gr. $\frac{1}{16}$ every four hours.

May 20th.—Bichloride increased to gr. $\frac{1}{16}$ every two hours.

May 27th.—Bichloride stopped. No effects noticed.

Case VI.—Daniel H——; nurse; widower; aged forty-six; admitted May 7, 1884. Disease, facial erysipelas.

May 7th.—Hydrarg. bichlor. was begun on May 10th; dose, gr. $\frac{1}{20}$ every hour during daytime.

May 12th.—Patient complained of pain in gums and profuse salivation. Hydrarg. bichlor. stopped. Treatment not resumed.

Case VII.—Dora V——; German; married; aged thirty-one; admitted March 31, 1884. Disease, phthisis pulmonalis, chronic diarrhœa.

May 21st.—Patient was given hydrarg. bichlor., gr. $\frac{1}{20}$ every hour. This was continued until May 23d with no obvious effect. It was then discontinued.

The following observations were made in private practice:

Case VIII.—Mrs. H——; puerperal peri-metritis with malarial complication. Bowels constipated; $\frac{1}{32}$ gr. bichloride given every hour for eleven hours, then $\frac{1}{16}$ gr. every hour for seven hours. Griping pain was then felt in the abdomen and three liquid evacuations occurred in rapid succession. Bichloride stopped, after which the diarrhœa ceased spontaneously. No stomatitis occurred.

Case IX.—J. B——, aged six years. Malignant measles with excessive temperature, $\frac{1}{20}$ gr. bichloride every two hours for three days. No irritation of stomach or bowels, no soreness of the mouth. The urine, which at first was very scanty, was increased to double the normal quantity. It contained no albumen.

Case X.—M. S——, six and one-half years of age; diphtheria following scarlet fever. Patient took $\frac{1}{25}$ gr. bichloride hourly, with very few omissions, day and night for a week, and the same quantity during the day with two or three doses during the night for several succeeding days. Chlorate of potash and tincture of the chloride of iron were given at the same time. The mouth was not affected and there was little or no irritation of the stomach or bowels. The urine was increased to seventy ounces, but fell to the normal amount when the drug was discontinued. It did not contain albumen during this time, though a very slight albuminuria was afterward developed.

Case XI.—Miss H. G——, fifty years of age, contracted kidney anasarca of legs; urine much decreased in quantity, but of high specific gravity, no nausea or other uræmic symptoms. One-twentieth of a grain in four ounces of water immediately produced gastric distress followed by vomiting. A second dose three hours later resulted similarly, and the patient declined to pursue the treatment further.

From an examination of these histories it will be seen that in five of the eleven cases, the bichloride given in quantities of from $\frac{1}{32}$ to $\frac{1}{16}$ of a grain, and at intervals of one or two hours, produced no ill effect. Of the other six cases diarrhœa with griping occurred in one, bloody diarrhœa in two, and ptyalism in two.

The bloody diarrhœa occurred in one case after seven hourly doses of $\frac{1}{20}$ grain the first day, and eight hourly doses on each of the four succeeding days. In the other case the drug was given in the same dose but at intervals of two hours throughout the day, and the bloody discharges occurred after four days. In both instances the diarrhœa ceased immediately on the withdrawal of the medicine.

Stomatitis occurred in one case after five days' use of the bichloride in hourly doses (during the *day*) of $\frac{1}{20}$ grain, and in the other case after two days.

In one case an idiosyncrasy caused gastric distress and vomiting immediately upon taking $\frac{1}{20}$ grain, and this recurred when the dose was repeated some hours afterward.

In one case of phthisical diarrhœa $\frac{1}{20}$ grain every hour for two days neither increased nor diminished the diarrhœa, producing in fact no obvious effect.

In two cases of children under seven years of age doses nearly equal to those given to adults were remarkably well tolerated.

In three cases, one of chronic diffuse nephritis, one of scarlet fever and diphtheria, and one of measles, the drug produced a marked diuretic effect.

In one case of phthisical hectic the temperature was apparently reduced in a marked degree by the bichloride.

ON THE PREPARATION AND USE OF OXYGEN AND ITS CONGENERS AS REMEDIAL AGENTS.

By SAMUEL S. WALLIAN, A.M., M.D.,

BLOOMINGDALE, N. Y.

(Continued from page 287.)

Methods and appliances for clinical exhibition.—As will be inferred, the use of these agents, although not necessarily restricted to these, is more especially adapted to office and hospital practice. For a complete office equipment in every considerable practice there should be at least three separate reservoirs. One should contain, at all times, pure oxygen, ready for instant use in cases of emergency; a second may contain pure nitrogen monoxide, and a third such modified admixture as is found best adapted to the class of cases under treatment. One or more additional reservoirs will at all times be found a matter of convenience, and in undertaking the treatment of a variety of cases in an extensive hospital or general office practice, quite essential. These should be arranged so as to be readily connected when desired. They may be placed in a suitable hall, closet, or private room adjoining the office, and connected with the latter either by ordinary gas-pipe or by rubber tubing. The latter may be neatly covered with rep or other suitable material, as a matter of taste.

The mouth-piece or inhaler may be of glass or hard rubber, and it is to be connected with the reservoir through covered rubber tubing and a glass bell, or a small-sized wash-bottle half filled (with simple water, a solution of caustic soda, or of any medicated solution desired), through which the gas is drawn in brilliant bubbles. A number of these bells or wash-bottles being kept on hand, each patient, or at least each class of patients, may thus be provided with an appropriate and separate solution.

In regard to proportions, a mixture very much used by me is composed of O two volumes, N_2O two volumes, and common air (to be drawn from a pure source) four volumes. In cases of extreme vascular torpor and functional inactivity a stronger mixture will be indicated, as O two volumes, N_2O one to two volumes, and common air one volume. Such a mixture is almost as efficacious, in emergencies and extreme cases, as pure oxygen; it is far better for ordinary use, and will answer every purpose in case of a sudden demand for the pure gas. Delicate patients will require the weaker mixture from the start, and after a few days of the more active treatment, very few cases will require any stronger. I would again most emphatically repeat what I have already several times asserted, that *a majority of experimenters with oxygen and congeners have failed and will continue to fail of good results on account of using the agents in too concentrated form.*

For a limited practice, in which one quality of gas must be made to serve a variety of patients, a compromise mixture of equal volumes of O, N_2O, and common air is as strong as should be used. This will be sufficiently potent for the severer cases, and must be cau-

tiously administered to susceptible patients and those in anything like a critical condition.

Time and frequency of administration.—Except in emergencies, the treatment should not be given either on an empty stomach or after a prolonged fast. In a majority of cases the mid-meal hours between breakfast and dinner are most favorable. It is well to avoid giving any active treatment within an hour of any principal meal, or at any time when there is present an unusual degree of fatigue. Mere weakness or nervous prostration do not, however, contraindicate, but are usually relieved by oxygen.

In cases complicated with persistent or periodic neuralgia, it will be advisable to supplement the regular daily sitting with a few inhalations just before retiring; and in these, as well as in extremely "nervous" or in hysterical cases, this evening exhibition should consist of as much as fifty per cent. N_2O.

As a rule, in ordinary chronic cases one treatment per diem is all that is advisable; in many cases it is all that is *allowable*. This should be carefully borne in mind by the inexperienced, since it is quite easy, and I had almost said natural, to overdo in the matter of dosage, in the anxiety of both physician and patient to see palpable signs of immediate improvement.

Methods, dosage, and intervals.—When feasible, let the patient stand erect, throwing the shoulders well back and as thoroughly as possible expelling the residual air from the lungs before inspiring the gas; then with a steady effort slowly inspire from the mouth-piece until the lungs are as full as they can be readily filled. Let the inspired gas be retained as long as convenient without discomfort, then slowly and deliberately expired. There should be an interval of from five to twenty minutes, according to the nature of the case, before a second inspiration is given, and during this interval the patient may walk about, sit, or recline, as he seems most inclined.

In ordinary non-critical cases, accompanied with venous stasis and general functional torpidity, from four to six inspirations, comprehending two to four gallons, may be given at each daily *séance;* but this limit should seldom be exceeded. Many cases will present in which two full inspirations will be all that should be exhibited during the twenty-four hours. In this regard the practitioner must be constantly on the alert, and must use the most careful discretion.

A systematic record should be kept of each case treated, beginning with a summarized history, a thorough physical examination, an examination of the urine, noting pulse- and respiration-rates, capacity of lungs, etc. The quantity per diem and specific gravity of the urine, as observed at stated intervals daily in critical or important cases, and at least weekly in all, during treatment, will furnish suggestive data from which to regulate the quality and quantity of gas to be exhibited.

If there be a tendency to hæmoptysis, oxygen is not necessarily contra-indicated, but evidently should be administered with more caution. I have not hesitated to advise the treatment in these cases, if not otherwise contra-indicated, and have never witnessed any untoward results; but the lungs should never be forcibly inflated, nor should the inspired gas be so long retained. As a further precaution, which, however, I am inclined to think is superfluous, it should be much diluted at the outset and gradually increased in strength with the progress of the case. I have even thought the use of the gas, with due precautions, has eventually lessened the liability to hemorrhage.

In acute cases, as of asphyxia from any cause, alarming dyspnœa, cyanosis, suspended animation, narcosis, severe paroxysms of asthma, etc., no definite rules can be formulated. The indications must be gathered in each instance from the nature and progress of the case, and the judgment of the practitioner must in all cases supersede all rules.

In cyanosis and asphyxia there is little danger of pushing the treatment too rapidly or too far, short of positively relieving the patient. The immediate demand is for *oxygen*, and it may be given, freely and constantly, until the imminent crisis has been passed and the urgent symptoms are relieved.

A practical suggestion.—In its incipiency every "new" treatment is called on to perform miracles, since at first only the most inveterate and apparently incurable cases will seek its aid. I would therefore utter this warning, and suggest that no such cases be received except with the express stipulation that the treatment shall be punctiliously followed for a definite period of, say, not less than two, three, or four months. It will be worse than throwing away time or than placing pearls before swine to permit the grand army of physical vacillators to spasmodically attempt the treatment, foolishly expecting that it will accomplish greater wonders than the touch of Midas' wand, and fully believing for a day that it is the latest "wonderful discovery" among patent nostrums. These will follow it for a few days or weeks, and will insist upon giving it up long before it has accomplished any definite or permanent good. They will be only a block of stumbling to its success with others, and will give you no end of annoyance by their irrational and short-sighted criticisms. Better decline to treat not only hopeless incurables, but all who will not stipulate to give the treatment a fair and thorough opportunity to accomplish tangible and permanent results. I would insist on this, even though it might appear to savor of the methods of the advertising charlatan. Thus, it would be a stroke of business prudence to charge each patient a maximum fee by the month for the first month, and minimum or perhaps graduated fees for subsequent months of treatment, since this will encourage perseverance on his part, and since the first month covers the period requiring most watchful care and intelligent adjustment of all the conditions.

Adjuvants.—As regards concurrent treatment by means of drugs, this must be left to the discretion of each practitioner, guided by the exigencies of each particular case. It must not be omitted whenever it rationally appears to be either synergistic or complementary. To reject any source of aid in treating maladies is to raise (or lower) any method of treatment to the questionable rank of a hobby.

Theoretically iron is an oxygen carrier, and in some instances it may be given with advantage during an oxygen course; but if the patient's diet be sufficiently varied so that it shall contain the earthy salts in due proportion, there will be little need for increasing the chalybeate element.

To this end, even though it may seem pedantic, I would distinctly urge, in connection with an oxygen course, the daily use of those cereal and other preparations known to be rich in phosphates and other needed elements, as oatmeal (coarse), white wheat (crushed or cracked), whole wheat flour, some of the principal elements of which are wanting in a majority of modern dietaries.

In connection with the use of oxygen the question of alimentation is of far more than usual significance. In all cases the diet should be thoroughly sustaining, and in some it should be abundant, even to the extent of forced feeding. Bearing this well in mind, no specific rules need be suggested. The necessity for an intelligently selected variety in diet suggests itself when we reflect that the subtle and powerful agent to which we are subjecting our patients rapidly permeates every molecule of matter in even the remotest tissues of the body. It accelerates at once the process of liberating worn material with retained and septic excretions, as well as that of rebuilding or repairing weakened structures. For all this work—destruction and reconstruction—liberal supplies of fresh material are in constant demand, and must be supplied with the food.

In all cases complicated by chronic gastric catarrh or

torpid states of any of the viscera, the somewhat overdone fashion of hot-water drinking, to the extent of two or three pints per day an hour before meals, will be found a valuable adjunct. If simple hot water be voted flat, hot lemonade or hot soda-water may be substituted, as indicated. The washing away of morbid products set free by the treatment is also quite an essential factor; hence, in addition to the hot-water drinking, the warm full bath, or a course of systematic bathing with massage, with also frequent local lavements, hot douches, etc., should not be omitted. These are invaluable adjuvants to any treatment.

The regulation of the general sanitary and hygienic surroundings of each patient need not be adverted to. The judgment of all intelligent practitioners will suggest this. One exception may be remarked in connection with this treatment: Deprivation in the matter of outdoor air and physical exercise, whether from negligence, necessity, or indifference, will not be so serious a drawback as in case of ordinary treatment, since superoxygenation to some extent supplies the lack. But blind faith in the treatment should not be allowed to exclude such aids as may be derived from any and all adjuvants.

I append reports of a few additional cases treated, hoping that other experimenters in this promising field may be prompted to give to the general profession the results of their efforts, and that in due time we shall not be, as now, literally without a literature on the subject.

Case VI.—Miss E. A. W——, aged thirty-one; superintendent of a fur manufactory, the confinement and dust of which is very irritating. Strumous habit, but family history negative. Is anæmic, despondent, and complains of a constant cough; areas of dulness over right lung, with persistent bronchial irritation and bronchial catarrh.

April 20th.—Placed this patient on a mixture of equal volumes of O, N_2O, and common air. Lung capacity but 130 cubic inches, although a woman of more than average stature and weight. Advised daily exercise in the open air and nutritious diet.

April 30th.—No apparent improvement; cough rather worse; expectoration very profuse, and sputa containing fetid cheesy (tubercular?) matter. Treatment continued.

May 10th.—Appetite rather better, and sleeps more regularly; otherwise no visible improvement. Cannot secure out-door exercise to any extent. Treatment changed to O two volumes, N_2O and atmospheric air, āā one volume. Lung capacity 150 cubic inches.

May 20th.—Lung begins to clear up, but no outward signs of improvement. Patient much discouraged, and only consents to continue the treatment on my positive assurance that she has made some progress. Lung capacity 160 cubic inches.

May 30th.—Now reports her general health as very decidedly improved; cough perceptibly better; her former sallow ("bilious") complexion has cleared up, and is now fairly ruddy. Eats and sleeps well, and enjoys a buoyancy of spirits unknown for years.

June 10th.—Reports herself "cured," and is loud in her praise of the treatment. Says she had no faith in it in the start. Her cough is almost entirely gone; respiratory murmur audible all over both lungs, and *has gained twenty pounds in flesh.* Lung capacity 195 cubic inches. Treatment discontinued, patient going to the country for a vacation.

August 8th.—She returns for additional treatment. Took a severe "cold" *en route* from the country, and her bronchial trouble returned. Severe passive congestion of both lungs, annoying cough with muco-purulent expectoration. Pulse, 94. At the first sitting she inhales two full inspirations of O one volume, N_2O one volume, and common air two volumes. Within five minutes her pulse falls to 84, and the immediate dyspnœa is decidedly relieved.

August 20th.—Some cough yet, but great general improvement is evident. Severe bronchial irritation persists, and, continuing the oxygen treatment, a local spray is added. ℞. Potas. chlor. ʒj. ad aqua ℥iv.; alternating every other day with ℞. Fl. ext. hyosc. ʒ ss. ad aqua ℥viij. per steam atomizer. Complains of pectoral and intercostal myalgia, for which ordered a stimulating lotion and tonic regimen.

August 29th.—Notable improvement is evident. Bronchial difficulty is much relieved; myalgia gone, and not much cough left. Treatment interrupted.

September 20th.—Treatment resumed every other day, improvement having continued since last record.

October 10th.—This patient now considers herself well, but is advised to leave the factory and live more out of doors, if possible.

Saw this patient six months later, and although she has not left the unwholesome factory she continues well.

Case VII.—L. P. N——, aged twenty-five; theological student; nervous temperament; family history good, but is a confirmed dyspeptic, and has spermatorrhœa of several years' standing, nocturnal emissions occurring almost every night. Over the latter he is despondent, even to desperation. Fears he is going into a "decline." Studies hard far into the night, preaches, becomes very excitable; after which he suffers from protracted insomnia. Has consulted a number of physicians here and elsewhere, but without benefit. Is now trying movement-cure, but thinks it weakens rather than strengthens him.

April 13th.—Begins the use of a mixture composed of O one volume, N_2O two volumes, and common air two volumes. Lung capacity 160 cubic inches; countenance expressing haggardness and hopelessness; urine loaded with oxalates.

April 20th.—Already reports a marked change in his appetite and digestion. Says his food no longer distresses him.

April 30th.—Nocturnal emissions have entirely ceased! He sleeps and eats well, and does not give way to excitement as formerly. Lung capacity increased to 190 cubic inches. Feels greatly encouraged.

May 10th.—Improvement has been constant and rapid since last report. Appetite and digestion excellent. Has gained in flesh, feels fresh and buoyant, and no return of emissions. In short, this patient is quite himself, and attributes the change wholly to the oxygen treatment. Lung capacity 200 cubic inches. No further treatment deemed necessary, and patient passed from observation.

Case VIII.—E. W——, aged forty-nine; insurance agent—one of the toughest of his kind! Could talk a graven image into taking a policy, if he had time. Mixes his family history so much with Farr's tables and the "actuaries' experience" that I cannot make much of it. Is suffering from a chronic "cold on his lungs," which I diagnose as bronchitis—sub-acute, with some pulmonary congestion. Has a very harassing cough, is quite dyspeptic, constipated bowels, harsh, dry skin, haggard appearance.

April 8th.—Placed him on the use, daily, of the standard admixture of equal volumes of O, N_2O, and common air. Lung capacity 150 cubic inches. Urine heavy with chlorides, etc.

April 16th.—Decidedly relieved; coughs less, raises more easily, sleeps and eats better. Treatment continued, increasing the proportion of O. Lung capacity 180 cubic inches.

April 25th.—Patient says he is pretty much "cured," and that the treatment has benefited his general health more than all the tonics, bitters, and "blood renewers" he has ever taken. Has a more natural appetite than for twenty years, and *is quite relieved of his habitual constipation.*

May 8th.—Reports himself "well;" no cough, respiration free and natural, all his bodily functions well performed.

Saw this patient six months later; no relapse.

Case IX.—Mrs. L. F. L——, aged forty-seven, married; one child, aged twenty. Family history shows rheumatism in her mother (arthritis, both sub-acute, and deformans), who is still living. Father dead. Brothers and sisters enjoy very fair health. Some twelve years ago had a miscarriage at three months, from which she made a poor recovery. Her account would indicate that the secundines were retained for several weeks, and finally expelled, with a spasmodic effort, and in a very fetid condition; pelvic cellulitis supervening and eventuating in chronic abscess (intra-pelvic), which four years ago found exit through a tortuous sinus and reached the surface in the right labia majora. Free incision was made, and the immediate or superficial abscess cavity was syringed repeatedly with tincture of iodine, carbolic acid, and glycerine. It healed but soon filled again, and a careful exploration with flexible probe proved its origin to be as above stated, the seat of the original abscess being, apparently, in the vicinity of the right ovary.

During the past three years patient has suffered from lumbo-sacral neuralgia and wandering arthritic pains. Six months since her neuralgia culminated in a painful and disabling sciatica of the left side. After exhausting all the domestic remedies to be had or heard of, trying salicylates, manaca, lotions, and anodynes without limit, she came to me in sheer desperation. I found her anæmic, suffering paroxysms of excruciating pain, which extended from the hip to the ankle; bowels constipated and moved only by enemas, dysuria a frequent symptom, appetite wanting, and much gastric distress accompanying the process of digestion. Tonics, iron, stimulants, counter-irritation, the deep injection of chloroform, and in some of the worst paroxysms, of morphia and atropia, as also the constant current, were all thoroughly tried, and afforded some temporary relief. However, these remedies severely aggravated her stomach troubles, inducing intense cephalalgia and almost unendurable nausea; and on omitting them the paroxysms returned with even greater severity.

As a last resort I advised a persistent trial of the oxygen treatment; and for the purpose of making the test a thorough one, took the patient into my own family. Her complexion is quite sallow, and skin, especially on her hands, covered with patches of "salt rheum," which has persisted for thirty years. She suffers from periodic attacks of rheumatic headache, and her countenance is a petrified epitome of seriousness and distress.

February 1st.—Prepared a mixture of O two volumes, N_2O two volumes, and diluted this with twenty per cent. of common air. Of this, two full inspirations to be taken at 10 A.M. and the same on retiring. Lung capacity 100 cubic inches. The first few doses of the mixture produced such complete muscular relaxation and semi-insensibility that she sank helplessly to the floor unless supported; no unpleasant sensations or effects supervening.

February 10th.—Sciatica still recurs, but less frequently and with less severity.

February 20th.—Appetite improves; complexion a little clearer; no dysuria except after the use of anodynes; discharge from the abscess less profuse and less fetid.

February 28th.—No further discharge from the abscess; digestion constantly improving; sciatica decidedly modified. Lung capacity 140 cubic inches.

March 5th.—Headaches less frequent and less severe; lameness almost wholly overcome; complexion rapidly improving. Patient eats, sleeps, and walks better, and shows a buoyancy of spirits unknown for years. Lung capacity 150 cubic inches. The treatment is continued with some interruptions, changing the proportions by adding twenty per cent. of common air and increasing to four full inspirations at each sitting, twice per diem.

March 12th.—Improvement steadily continues in all directions.

March 20th.—Is gaining flesh quite perceptibly, but *it is as much a gain of quality as quantity.* Paroxysms of headache rare and light; sciatica persists, but is mild. "*Salt rheum*" *gone; skin smooth as a child's.*

April 1st.—She declares she is ready to "certify" to any kind of statement I may ask as to the efficacy of the oxygen treatment. Avers that it has made her "a new woman," etc. Wants to go home. I express my conviction that the treatment should be continued much longer to ensure permanent results. She goes home, promising to return soon, especially if any old symptoms reappear.

April 24th.—Has worked considerably about the house and garden since last report. General health continues good, but sciatica returns in mild form. Again place her on four inspirations daily of equal volumes of O, N_2O, and common air. Lung capacity 200 cubic inches.

May 3d.—Steady improvement since last report. Sings with good voice, which she has not done for years; walks and rides without pain or extra fatigue; also does considerable light work about the house. Her complexion is now clear and fairly ruddy; headaches slight and infrequent. No sciatica, no eczema.

May 18th.—Treatment suspended. This patient has astonished her friends—*and her physician!*

September 15th.—Continues to this date free from all her former complications, with the exception of occasional disturbances of a physiologically weak heart. These are, however, chiefly or wholly attributable to her own indiscretion in the matter of over-exertion. She has attended to active household duties ever since treatment was suspended.

THE USE OF THE GREEN LEAVES OF THE DATURA STRAMONIUM IN THE CURE OF PAINFUL JOINT AFFECTIONS.

By HAL C. WYMAN, M.D.,

PROFESSOR OF PHYSIOLOGY AND HISTOLOGY, MICHIGAN COLLEGE OF MEDICINE, DETROIT, MICH.

It may seem unwise to speak of the use of a remedy that can be had only at one season of the year, yet such a remedy I have found so invaluable and wide in its range of usefulness that I am constrained to risk criticism by reporting the success I have had in the treatment of various painful joint affections with the green leaves of the datura stramonium. I have now under my care, in the wards of the Michigan College of Medicine Hospital, a young woman, aged twenty-two, who is recovering from an attack of acute rheumatic inflammation of the right knee-joint, that illustrates the advantage of treatment with the fresh stramonium leaves. She was attacked three months ago with rheumatism of wrist and ankle-joints upon opposite sides. Under treatment with salicylates the swelling disappeared from these joints and reappeared in the right knee, where it remained until I began the use of the leaves. In the meantime, blisters and iodine ointment externally, iodide of potash, colchicum, and alkalies internally were tried without avail. Large and frequently repeated doses of morphine were required at night to relieve pain and produce sleep. She began to enjoy freedom from pain, and to sleep, and the joint to improve, immediately the joints and parts contiguous were enveloped in layers three or four leaves deep of the freshly picked leaves of the datura stramonium—thornapple or Jamestown weed, as it is sometimes called. This application has been continued for two weeks. Internally she has taken infusion of quassia only. She has developed good appetite. The joint has become mobile and supple, and swelling is almost entirely gone.

A feeble, nervous boy, aged ten, had psoas abscess caused by carious dorsal vertebræ. He slept badly and cried and worried with pain in the hip and lumbar region.

Morphia internally interfered with digestion. His friends could not be prevailed upon to use it thoroughly by inunctions. I directed that a sufficient number of the fresh leaves of the stramonium be gathered daily from a neighboring vacant lot and applied to the hip and lumbar region, and held in place by a bandage. Freedom from pain was an almost immediate result.

I could mention numerous cases of acute inflammation of the large joints of the body where great pain, on attempting motion, was a prominent symptom that have occurred in my practice during the summer season. I have been in the habit of using the fresh stramonium leaves in these cases, and with the most happy results, so far as the relief of pain is concerned. In the season when it is impossible to obtain the fresh leaves I have tried, but without success, to obtain the same results by inunctions of stramonium ointment.

The plant from which the leaf is obtained is now so common in the United States that one need experience little difficulty in getting a sufficient number of the leaves fresh every day for use in any case of inflamed joint, where it is desirable to check pain and give physiological rest. It is my custom to keep the inflamed and painful joint enveloped in the leaves for a period of twenty-four hours, when fresh leaves are to be applied. In some instances I have used the bruised leaves in the form of paste or cold poultice, but do not think any particular advantage has resulted from this method of application. All that seems to be necessary to relieve the pain in an inflamed joint is to invest it with a layer of leaves thick enough to shut out the air, and prevent surface evaporation. Profuse perspiration from the skin over the joint follows, and pain and swelling usually vanish.

An experience of twelve summers with this remedy convinces me that with its help there is less frequent occasion to resort to the various immobilizing apparatus in the management of joint troubles than during the winter, when it is impossible to procure the fresh leaves, and that my summer cases make better recoveries —more useful joints—because of the greater opportunity given by the treatment without fixation apparatus for the exercise of the physiological conditions under which joints exist.

Progress of Medical Science.

Opium-smoking as a Therapeutic Measure.—Dr. Thudichum regards opium-smoking as a valuable remedy in colds, hay fever, chronic neuralgia, and hyperæsthesia, when these affections are rebellious to the action of quinine in large doses (*Schmidt's Jahrbücher*, No. 4, 1884). It is also useful in attacks of coughing in phthisical patients. The author thinks there is no danger of the patient becoming habituated to the practice, and says that those only who suffer from incurable affections are unable to cure themselves of the habit. The aqueous extract is used and the smoke is to be deeply inhaled. Dr. Thudichum regards the stories which have been told of the victims of opium-smoking as highly colored fables, but this is probably because he lacks experience, otherwise he would not so unhesitatingly recommend such a dangerous remedy.

Experimental Research Relating to the Etiology of Tuberculosis.—Geo. M. Sternberg, M.D., F.R.M.S., Major and Surgeon, U.S.A., in a paper read before the Section of Biology of the American Association for the Advancement of Science, stated that he had repeated Koch's inoculation experiments, and was able to confirm him as to the infectious nature of tuberculosis. Also as to the presence of the bacillus discovered by him, in tubercle nodules in the lungs and in tuberculous glands of inoculated rabbits and guinea-pigs (inoculated with sputum, containing the bacillus, from a phthisical patient). The experiments of Formad of Philadelphia, by which he claims to induce tuberculosis in rabbits by the introduction into the cavity of the abdomen of finely powdered inorganic material, have also been repeated with an entirely negative result, so far as the production of tuberculosis is concerned. The conclusion is therefore reached that the bacillus of Koch is an essential factor in the etiology of the infectious disease, tuberculosis.

Intermittent Fever Excited by Intestinal Worms.—Dr. Rousseau relates in *L'Union Médicale*, No. 30, 1884, the case of a young woman, nineteen years old, who was attacked with an intermittent fever of very severe type. The attacks recurred at frequent intervals for over a year, during which time the patient became emaciated and suffered severely in her general condition. Quinine and other antipyretics were tried repeatedly without effect. Finally several ascarides were passed, and an anthelmintic treatment being then ordered two hundred and twenty-nine worms were passed in four months. The intermittent attacks at once ceased and did not recur.

Paraldehyde as a Hypnotic.—Dr. C. Rank formulates the following conclusions based upon a number of experiments with this remedy: 1, On account of its unpleasant odor and burning taste, paraldehyde is unsuited for general use, especially in private practice; 2, in physical diseases it exerts no hypnotic effect, at most its action is only sedative; 3, paraldehyde is efficacious in nervous insomnia, in mental excitation, and especially in delirium tremens; 4, this drug cannot replace chloral or morphine, at least in the treatment of physical disorders.—*Deutsche Medicinal-Zeitung*, August 11, 1884.

Exanthem following the Use of Antipyrin.—Dr. Paul Ernst reports, in the *Centralblatt für Klinische Medicin* of August 16, 1884, two cases of an eruption caused by the internal administration of antipyrin. The two patients were a boy and a woman, aged respectively ten and sixty-seven years, yet the eruption was so nearly alike in both cases that there could be little doubt that the same cause was at work. The exanthem consisted of little irregularly rounded pimples lying close together, and in some places confluent so as to form patches of greater or less extent, between which the skin was normal, thus giving a marbled appearance to the surface. After about five days the eruption began to fade and to assume the character of a brownish pigmentation, and in the old woman there were some faint evidences of desquamation. Traces of the eruption were still visible at the end of two weeks. The exanthem was thickest over the body, and on the extremities the extensor surfaces were more covered than the flexor. In the boy there was some œdema of the face, but in neither case was there any eruption on the head or neck, although the palms of the hands and soles of the feet were not spared. There was some itching in the case of the woman, but the boy did not complain of this. The eruption ran its course and disappeared, although the administration of the antipyrin was not interrupted. The writer explains this by supposing that the system acquired a tolerance for the drug. On this account he advises a continuance of the remedy where its use is indicated, despite the eruption. In a postscript Dr. Ernst states that he has observed three other cases of an exactly similar nature.

Osmic Acid in Epilepsy.—Dr. Wildermuth has given osmic acid in a number of cases of epilepsy occurring in his practice during the past two years (*Centralblatt für Klinische Medicin*, August 16, 1884). It was given, in combination with potassium, in pills, containing each $\frac{1}{1000}$ grain of the salt. The largest amount given in one day was $\frac{1}{6}$ grain. He used it in ten inveterate cases, and saw no result in seven, in two the attacks were less frequent, and in one a prompt improvement and final cure was obtained. The drug caused no unpleasant symptoms of any kind.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, September 20, 1884.

THE WAVE THEORY OF MENSTRUATION.

So rapid has been the progress of scientific investigation and destructive criticism that there is now no English or American text-book which presents correctly the state of scientific opinion regarding the physiology of menstruation. It is still generally stated that menstruation is a miniature pregnancy, in which there is a disintegration and throwing off of the mucous membrane. It is known now, however, that such statements do not express the truth, but that the denudation is only partial, and that the blood escapes mainly by diapedesis and by rupture of engorged vessels. This view, that the uterine mucous membrane is characterized by a monthly "deciduosity," has been laid aside.

In the same way the old theory of Pflüger, that menstruation and ovulation were almost, if not quite inseparable phenomena, the irritation of a ripened follicle exciting reflexly uterine congestion, has also been disproved. The fact that after removal of the ovaries menstruation may continue, furnished a sufficient refutation of this previously very satisfactory explanation of the menstrual process.

If, however, it be true that menstruation invariably ceases after removal of the Fallopian tubes, some ingenious person may yet be able to rehabilitate in a measure the reflex hypothesis of Pflüger.

At the meeting of the German Naturalists and Physicians in Freiburg, February, 1883, Professor Hegar reviewed and showed the insufficiency of the various theories of menstruation. Since that time Arthur Farre and Leopold (*Archiv f. Gynecologie*, Bd. xxi.) have contributed further evidence as to the independence of ovulation and menstruation.

In a recent issue of Volkmann's *Klinischer Vorträge* (No. 243), Dr. Carl Reinl, a pupil of Hegar, discusses the theories of menstruation, and contributes the results of some careful experiments relating to what may be called the wave theory of menstruation.

Professor Goodman, of Louisville, some six years ago, advanced the theory that the vital activity of woman ebbed and flowed rhythmically, the length of the wave being the duration of a menstrual epoch. Various investigators (Putnam-Jacobi, Stephenson, Rabuteau, Hennig, and Von Ott) have contributed some facts which apparently show that just before menstruation the vital powers of woman are at the highest, and that with the appearance of the menses there is a gradual fall, with, in some cases, a secondary rise.

The measures of this alleged increased vitality have been the state of the heart circulation, the temperature, and the excretion of urea. It has generally been found that the temperature has been higher, the blood-pressure greater, and the excretion of urea larger in amount before menstruation than during or directly after it.

Reinl's observations cover the subject of the relation of the heat production to the menstrual epoch. Records were made of the temperature in eighteen cases. Eight of these were healthy women; on three ovariotomy or oöphorectomy had been performed, while the remainder had some form of uterine or ovarian trouble. In the healthy patients he established the existence of a temperature curve, which reaches its highest point just previous to menstruation; it then gradually falls during menstruation, and for some days thereafter. In a certain proportion of cases during the first half of the intermenstrual period it falls below the normal.

In the pathological cases Reinl still found marked evidences of the temperature wave. Even when menstruation occurred every two or three weeks the appearances of menstruation corresponded with the top of the curve. Perhaps the most significant fact, however, was that in the castrated women, when no menstruation occurred, the form of a periodically returning temperature wave could still be made out.

The observations which have thus apparently established the fact of a menstrual wave are most interesting and not without practical significance. It will still be questioned, however, whether because the pulse is harder, the skin hotter, and the urea excreted greater, therefore the vital powers are above their average of activity.

MALARIA AS A DEFENCE IN A SUIT TO RECOVER RENT.

THE defence of poor plumbing to a suit to collect rent is a common one, and it often seems to be the opinion that defects of this kind causing sickness are sufficient in law to prevent a recovery on the part of the landlord.

So generally is this defence brought forward, that it shows there is a deep-seated idea that this is an exception to the ordinary rule of contracts. There may be defects in the roof, or the furniture may not be up to the standard promised by the landlord, but such defences are not often urged in a suit for rent. It is only when malaria shows itself that the tenant feels himself justified in leaving the house or in refusing to pay his rent.

There seems to be no reason, however, for this general belief in the power of malaria to change the settled rules of law. When a man hires a house and examines it, he cannot, in general, refuse to pay rent because malaria then existed or is afterward produced because of poor plumbing. He takes the house as it is, and while he may be unfortunate in his selection, he will not be allowed to leave, and certainly there is no rule of law which will allow him to continue in the house and yet refuse to pay rent.

In the case where there is a positive guarantee on the part of the landlord that the plumbing is in good order and no malaria exists, there seems to be a little confusion in the decisions, but the general opinion is, that if,

notwithstanding the guarantee, the tenant examines the house and is apparently satisfied by accepting the lease, he cannot afterward refuse to pay rent. In case the tenant relies on the landlord's statements and makes no examination of the condition of the house, the decisions are in favor of allowing him to leave the house, and no rent can be recovered.

An interesting case was decided not long since in this city which seems to give the tenant rights under the Health laws to leave his house and refuse to pay rent. The following is the statement of the case: "In a suit for rent claimed to be due from a tenant of a suite of rooms in an apartment house, it appeared that the defendant's wife and servants were taken sick by inhaling a malarial or poisonous gas in the apartments occupied by them; that this unhealthy condition of the apartments was owing to the defective condition of the general plumbing work of the house, of which the landlord was notified by orders received from the Board of Health, requiring him to have changes made in the plumbing work, and which unhealthy condition could have been removed if he had complied with those orders; that the defendant waited for two weeks, and finding that nothing was done on the part of the landlord, left under the apprehension that he was imperilling the health of himself and family by remaining." Under these circumstances, the judge who tried the case decided that this was what is called in law a constructive eviction, and the tenant could not be forced to pay rent during that portion of his lease subsequent to the removal.

The decision has recently been affirmed by the General Term of the Court of Common Pleas, and unless reversed by the Court of Appeals, which is unlikely, will be the law in the future. It may be said in general that the policy of the law is becoming more favorable to tenants in some particulars, but the main principles of contract law will always apply to leases.

WHEN SHOULD POISON LABELS BE USED?

A CASE has recently occurred in Philadelphia which raises a nice question as to what prescriptions should be labelled "Poison." The Pennsylvania statute, and that of almost every other State, is to the effect that "No apothecary, druggist, or other person, shall sell, . . . by retail, any morphia, strychnia, . . . except upon the prescription of a physician or on the personal application, . . . and in all cases of such sales the word 'Poison' shall be carefully and legibly marked or placed upon the label," etc.

In the case referred to a physician ordered pills containing one-twentieth of a grain of strychnia for a patient; a number of persons (not previously adjudged lunatics) believing that such diminutive pills could contain nothing prejudicial to health, undertook to see who could swallow most of them in a given time. The youngest of the party took fourteen, representing seven-tenths of a grain, and died. The erudite coroner, after holding an inquest of great length, has instructed his jury to find the dispensing clerk responsible for the death of the girl in not labelling the pill-box "Poison."

Aside from the fact that from the manner in which the case has been conducted, it looks very like a case of libel, the question arises, Are all prescriptions containing a poison to be labelled "Poison"? or shall only those prescriptions containing the drugs mentioned in the statute be labelled as poison? The statute in the Pennsylvania books is clearly deficient, as it only includes morphia, strychnia, arsenic, prussic acid, and corrosive sublimate. Certainly it would be absurd to require the apothecary to label pills containing one-twentieth of a grain of strychnia "Poison," and at the same time allow him to sell an ounce of tartar emetic or one grain of atropine to any person without the cautionary label. Yet this is clearly what the law would allow, and we do not see how he could be prosecuted for it. But it is equally absurd to require him to put the poison-label on every prescription containing a poison; for in this case it would be the exception when a prescription would not be labelled as poisonous. Brown-Séquard's neuralgic pills, Dalby's carminative, Mitchell's tonic pills, Dover's powder, and fully one-half of the prescriptions sent out by physicians would be illustrated with the skull and cross-bones. Such is clearly not the purpose of the law, and it would be not only absurd but puerile, especially when pills are dispensed, as no one could take two pills by mistake for one; and though the law has a good deal of presumption, it has no right to presume that the physician is prescribing for a patient whose friends are without proper mental balance. Had the prescription in question called for gr. v. of strychnia, and f℥ xiiss. of water, in teaspoonful doses, the druggist would very properly, as he says, have labelled it as poisonous, because a careless person might take a tablespoonful of it, or else, as many people do, might turn the bottle up to the mouth and guess that the proper amount had been swallowed. As an example of the absurdity to which this hair-splitting construction of the law would be reduced, the druggist in question gives the following, taken from his file: "Eight suppositories, each containing half a grain of aqueous extract of opium. Use one" (here the opium contains morphia, and the label must be used); and adds, "If some lunatics will banter each other as to how many of these they can insert into their respective rectums, they will also be subjects for inquest." But the manifest absurdity of the coroner's construction is still further seen when it is remembered that scores of patent medicines are sold without the poison-label; in fact, we do not remember ever to have seen such a label on a patent-medicine bottle. Yet we have known a woman to die within two minutes after taking a triple dose of a patent cough-mixture, without previously shaking the bottle. Nor have paregoric or any of the many soothing syrups cautionary labels. The Philadelphia coroner may not be much of a mathematician, but he has evidently not forgotten the *reductio ad absurdum*.

MULLEIN LEAVES IN PHTHISIS.

AT the late meeting of the International Medical Congress at Copenhagen, Dr. Quinlan, of Dublin, read a paper in which he advocated the employ of mullein leaves in phthisis, claiming extraordinary success in the treatment of this disease by the free use of a decoction in milk of this plant, or rather *weed*, for it is one of the most common of our native weeds, growing by the roadside and in

neglected fields. Mullein is known to botanists as the verbascum thapsus, and has honorable mention in the Codex of France under the name of *Molène, bouillon blanc;* entering into the composition of the *quatre fleurs pectorales*. The mode of preparation is to infuse an ounce of the dried leaves, or the equivalent of the fresh, in a pint of milk, to boil for ten minutes, and then to strain. This infusion is administered warm to the patient, with or without a little sugar. The whole pint is given in two doses during the twenty-four hours. The hot decoction is said to be very easing to consumptive coughs, so that during its use the ordinary cough mixtures may be dispensed with. Its power of checking phthisical looseness of the bowels is said to be very marked. In early cases, according to Dr. Quinlan, the mullein milk appears to act very much in the same manner as cod-liver oil, than which it is much more palatable. A large number of cases of pulmonary consumption have been treated in St. Vincent Hospital, Dublin, exclusively on mullein, and it is said that crowds of patients have been attracted to this hospital by the wonderful results which have been obtained from this singularly simple treatment. In phthisical coughs great relief is said to follow smoking dried mullein leaves in the same manner as tobacco. Dr. Quinlan showed at the meeting of the Congress cigarettes made of mullein leaves, which are said to be very pleasant to smoke. It is asserted that in pretubercular and early cases of pulmonary consumption mullein appears to have a distinct weight-increasing power, and to be an excellent palliative to the cough in the later stages, besides being the very best remedy to antagonize looseness of the bowels.

Wood, in the U. S. Dispensatory, speaks of mullein leaves as "demulcent and emollient," and as reputed to possess "anodyne properties which render them useful in pectoral complaints."

THE NEXT MEETING OF THE INTERNATIONAL MEDICAL CONGRESS.

It is a matter of gratification and pride that the International Medical Congress has decided to hold its next meeting in this country. The American profession, however, cannot too soon be made to feel that it has accepted no small responsibility, and that it must put forth especial effort in order to acquit itself well. So far as American hospitality and the ability generously to offer it are concerned we have little to fear. But that the literary and scientific contributions come up to the high standard heretofore observed in these Congresses is a matter of more concern. Unquestionably American physicians can respond successfully in this direction if the effort is made, as there is little doubt will be the case. We trust that our readers will begin at once to consider whether they wish to take part in the Congress, and if so, to see that they bring to it something worthy of the occasion. Three years is none too long to expend in such preparation.

Naturally, the character of the papers read at the Congress in question will depend greatly upon the judicious work of the organizing committee. There should be no effort spared to get our most representative men and no ill-timed charity in selecting the wheat from the great amount of chaff that will surely be offered. No papers sho ild be accepted that do not bear the stamp of originality and merit.

Some practical difficulties will, we fear, be met with by reason of the climate of Washington, where the Congress is to be held. In July and August the heat is liable to be intense, and to unfit even the most enthusiastic for scientific work or social enjoyment. It would be impossible probably to get many European physicians from their work so early as May or June. In September there might perhaps be cooler weather.

Still we do not think that climatic objections will be insuperable, especially since the hotel accommodations in Washington are so ample, and the Potomac has almost always a cool breeze. Three years from now, however, we shall advise our prospective European visitors to bring the lightest clothes and to be prepared for the most liberal diaphoretic activity.

THE GROSS MEMORIAL AGAIN.

The sting of death is sometimes in the imbecility of posthumous admirers. The *Chicago Medical Journal and Examiner* has made a surprising display of unpleasant feeling as regards the position of The Record toward the proposed Gross Memorial Professorship. We have not seen so near an approach to billingsgate in a medical journal for a long time.

We confess that we do not understand the cause of the *Journal's* outburst. We honor the memory of the late Dr. Gross; we urge that his memory have a fit memorial. His is the greatest name in American surgery; we protest against its being buried in a "memorial professorship" in a private (as distinguished from a State) medical school. Medical history furnishes no such project as that which is now being set before us. We advise against it because the plan is unwise and will not arouse the sympathy of the profession. We urge in its place that there be founded a memorial laboratory or a lectureship similar to those by which celebrated physicians of London have been honored. Every doctor in the country, with a spark of generosity in him, will gladly forward such a plan, and it will succeed. But to set up as a memorial to a great man a didactic professorship for the yearly benefit, not of doctors, but of students, a commonplace, utterly local and never-to-be-forgotten investment is ridiculous!

The *Journal* is mistaken in arguing with so much point and courtesy that The Record is "untruthful," "jealous," "spiteful," and "sordid." It is simply a question of properly and successfully rendering homage to a distinguished name. We believe thoroughly that Jefferson Medical College took up the matter in good faith and in perfect unselfishness. We do say, however, that it was not only unwise but in bad taste for it to organize a scheme which will help itself as much as it honors Gross. We have the "effrontery" still to reiterate that the above expresses the views of most of the profession.

If the *Journal* still believes that our interpretation of the general feeling is not correct, we refer its editor to *Gaillard's Medical Journal*, the *Medical Age*, the *Detroit Lancet*, the *Cincinnati Lancet and Clinic*, the *Indiana Medical Monthly*, the *Peoria Medical Monthly*, with other journals yet to come.

It is said that Lord North's third wife was of so inflammable a temperament that for three days before the wedding she had to be kept packed in ice. We would in all courtesy suggest that a similar course would be advisable for the editor of our valued contemporary previous to his ventures in polemics. Being cooled to below the point of unmannerly vituperation, he may see that possibly all is not guile in New York, and that we may be quite sincere in urging the views we have presented.

We certainly trust that there will be no quarrel over the matter. It would require very little change to secure perfect unanimity in working for the honor of the lamented Gross.

As bearing upon the general question, we append the following from a well-known Jefferson Alumnus in the western part of this State. The writer puts the case with fairness, and is responsible for his facts:

Your views on the subject of the proposed memorial to the late Professor Gross meet with a hearty response from many of the alumni of Jefferson Medical College. As a member of the Auxiliary Committee, appointed to solicit contributions, I find that most of the old "Jeff." men whom I approach are unwilling to help in any movement which will, at the expense of the alumni, only give another prize to be electioneered for in the Board of Trustees of the College. All old Jefferson men know what a close corporation said Board is, and when they remember that neither Professor Pancoast nor Professor Gross, out of their large estates, left a cent to the school which so long honored them, it would seem that these great men saw nothing in the spirit which animates the Trustees to warrant giving them the disposal of any endowed chairs. The last three appointments to professorships in Jefferson were made notoriously for the following objects—first to conciliate Philadelphia society, and, second, to draw students from the West. It is high time that the alumni of a college, who in after life do so much for its benefit, should have some voice in the management. Let the Alumni Association have the election of one-half the Board of Trustees, or a confirmatory vote on professional appointments, or the nomination to the Trustees of names to fill vacancies in the teaching body, if they are to be expected to aid the College in the means for higher education. I am as fond of my alma mater as the next man, and look with pride at the signatures on my diploma, but I cannot avoid the chagrin which comes over me every year as I peruse the annual announcement, and see the miserable subterfuges which are inserted therein to appease the clamor for higher standards and yet avoid any rock which will lower the fees of the Faculty. Such an instance is found in the last announcement, in which the preliminary examination required by the laws of certain States is offered only to those who intend to locate in those States, instead of being required of all students. The *auri sacra fames* has its seats in the councils of all our educational institutions, but the alumni of Jefferson will not, as a body, respond to that thirst until a change comes over the spirit of those who control its affairs.

A JEFFERSON MAN.

THE FORT PLAIN FASTING GIRL.—Dr. Darwin Potter, of Fort Plain, N. Y., has examined the alleged fasting girl of that place. He finds the case to be one of very much the kind we had stated. The claim to having fasted for one hundred and eighty-eight days is made preposterous by the girl's well-nourished state. She has chorea, and is, as we suggested, undoubtedly hysterical.

News of the Week.

THE RHINELANDER CASE.—The recent investigation into the mental condition of William C. Rhinelander by a commission appointed by the Court of General Sessions has attracted a great deal of attention on the part of the community at large. It was begun for the purpose of enabling Recorder Smyth to decide whether Rhinelander should be called upon to plead to an indictment for assault upon John Drake, a lawyer of this city. It was alleged that Rhinelander was insane and more fit for an asylum than a trial in a court of law. The investigation continued for a number of weeks during the summer before the commission, consisting of Drs. Detmold and Nolan and Edward Patterson, a lawyer. The testimony was conflicting and Rhinelander vigorously contested the idea that he was insane, claiming that he desired and ought to have a criminal trial. The commission have just reported to the Recorder, Drs. Detmold and Nolan holding that he is insane, and Mr. Patterson that he is not. Under the law the Recorder can adopt either report he chooses, and he is now engaged in examining the voluminous testimony produced, in order to arrive at some conclusion.

THE DEATH OF DR. ROBERT J. HEINMÜLLER.—At a special meeting of the members of the Fourth Division of the Health Department of the City of New York, held September 2, 1884, the following resolutions were adopted:

Whereas, We have learned with deep sorrow and regret of the death of our late colleague, Dr. Robert J. Heinmüller; therefore, be it

Resolved, That in the death of Dr. Heinmüller, this Department has lost one of its most faithful and efficient officers, and we, his associates, a friend whose many noble qualities of mind and heart had endeared him to each and all of us; and the profession has lost one of its most promising young members.

That we tender to the family of the deceased our deepest sympathy in their great bereavement.

That a copy of the proceedings of this meeting be sent to the family, and to the medical journals for publication.

J. B. TAYLOR, M.D.,
J. B. LENEHAN, M.D.,
GEORGE S. CONANT, M.D.,
J. N. MCCHESVEY, M.D.,
J. C. CONOVER, M.D.,
Committee.

THE CHOLERA.—On September 14th, the cholera at Naples showed evident signs of abating. On the 16th, there were only 470 new cases and 167 deaths. The total number of deaths at Naples, up to the day mentioned, is estimated to be about 3,700. This would represent between eight and nine thousand cases, since the mortality has been, on the whole, rather below its average. In other parts of Italy the cholera continues to keep its hold, but makes no alarming progress. Reports are sent in from thirteen different provinces, but the total number of cases ranges between one and two hundred, with a mortality considerably less than fifty per cent.

In France there continues to be occasional sporadic

outbreaks. Some cases are still reported from Toulon and Marseilles. In the Eastern Pyrenees there are forty-seven places where the disease has appeared. In all France it is estimated that there have been 5,200 deaths in 207 cities and villages.

Cholera is reported from half a dozen Spanish towns, but in none of them has the disease made great ravages, if we may trust reports. At date of writing, indeed, there have not been 200 deaths from cholera in all Spain. On the whole, the epidemic appears to have spent its force. We may estimate that it will leave with a record of 10,000 deaths and two or three times as many cases of sickness.

The Academie de Medicine, of Paris, has appointed a cholera commission, consisting of MM. Brouardel, Marey, Rochard, Proust, de Mussey, Fauvel, Legouest, and Besnier.

Protesting against Compulsory Vaccination.—A despatch says that over 3,000 people at Leicester, England, have been summoned for defying the vaccination law, the feeling against which is very bitter all over England.

Giving Commissions on Dental Patients.—We are not aware that there is an Odontological Code of Ethics, written or unwritten. But whether there is or not, there ought to be some moral prohibition put upon the practice by certain dentists of offering a percentage on all patients sent. The practice seems to be to circulate cards among physicians announcing that "we allow you twenty-five per cent. of all money received from patients whom you send us."

The English Army Surgeons, about two thousand in number, are to change their uniform from scarlet to blue.

A Testimonial to Dr. H. D. Schmidt.—We learn from the New Orleans *Medical and Surgical Journal* that the friends of the eminent pathologist, Dr. H. D. Schmidt, have organized for the purpose of procuring and presenting a testimonial portrait of him to Charity Hospital. The presentation was to have been made the first Monday in September. Dr. Schmidt is *facile princeps* the pathologist of the South, and deserves this act of appreciation from the profession.

The Will of the Late Dr. John G. Adams.—Dr. Adams, by his will, bequeaths $5,000 to the Presbyterian Hospital for a free bed for the sick poor of the Fifth Avenue Brick Church; $2,500 to the Bridgeport Protestant Orphan Asylum and Hospital; $500 each to the Physicians' Mutual Aid Association and the New York Training School for Nurses. His medical library is bequeathed to the New York Academy of Medicine. Dr. Adams revokes in a codicil a bequest of $5,000 to the New York Academy of Medicine.

Cholera and Tobacco.—There seems to be a belief, among the newspaper section of the city at least, that tobacco has some prophylactic power against cholera. The *Times* correspondent who visited Toulon and Marseilles kept tobacco in his mouth while in the infected districts and hospitals. Mr. George Augustus Sala has asserted that in past epidemics tobacco-smokers have had some exemption from the disease. Now experience has shown that acid solutions prevent the development of the cholera germ, and that this organism cannot easily pass through an acid stomach into the intestine. But the use of tobacco promotes a flow of alkaline saliva which is swallowed, thus preparing a flowery path for the bacillus to enter.

Prof. Mallet, M.D., LL.D., Ph.D., has been appointed to the chair of Chemistry in Jefferson College, as successor to the late Professor Rogers. The school, in selecting Dr. Mallet, has successfully pursued its policy of taking the best men obtainable for its professorships.

Trouble among the Homœopaths at Washington, D. C.—The homœopaths, or at least certain persons practising under that trade-mark in Washington, D. C., are complaining that the trustees of the Garfield Memorial Hospital give them no share in its management. To offset this, the managers of the "National Homœopathic Hospital" (that is to be) have issued an appeal to the homœopathic societies throughout the country to assist in a grand national fair to be held in Washington in December next.

A Homœopathic Fraud Exposed.—While on the subject of homœopathy, it may be of interest to note the following case of poisoning recently reported in the *Australasian Medical Gazette*: "A homœopathic practitioner named Günst was called in to attend a young woman suffering from sleeplessness and neuralgia, for which he prescribed morphia and quinine. His explanation is that by some bungling in the use of Hahnemannic symbols, the powder ordered actually contained ten grains of hydrochlorate of morphia and five grains of quinine, and as the directions given to the patient had been to take the powder at once, the unfortunate woman was killed. This accident of the poisoning, however, is not the main point of interest now. In the evidence given by Dr. Günst at the inquest, he explained that what he intended to order was half a grain of morphia, and this admission at once puts the treatment out of the compass of homœopathy."

The Code of the Nebraska Doctor.—The Omaha doctors are being greatly slandered or they are in a bad way. A correspondent from that city asserts that the code of ethics is "Every man for himself and the devil take the hindermost." This code is recommended, however, by a Western exchange as being devoid of all possible hypocrisy at least.

The Missouri State Medical Society is accused, like the New York Society, of being overrun with specialism. There is fault on both sides. Papers are wanted, and specialists generally are the most ready to write. Let the general practitioner assert himself, therefore, but also let the organizing committees help him a little more than is now the case.

Pasteur in Wax.—A foreign exchange states that there has been placed in the Musée Grévin a representation in wax of Pasteur, with his assistants engaged in the act of inoculating a dog against rabies. Wax works have become the modern barometers of fame.

The Important Fact is being circulated that Mr. Blaine is homœopathic in his medical beliefs. However this may be, he seems a big pill to some people.

Excision of the Pylorus for Malignant Disease was performed by Dr. Randolph Winslow, of Baltimore, recently at the University Hospital. The patient was a woman, forty-two years of age, who had suffered for over a year and was much emaciated. She died of shock a few hours after the operation. So far as we can learn, this is the second operation of the kind in this country. Both have been unsuccessful.

Doctors in Denver.—The *Denver Medical Times* says, that about twenty new doctors have located in Denver within the past three months. The ratio of doctor to inhabitant now is one to two hundred and fifty. Denver has also one medical college, twenty-five to thirty professors, and five or six hospitals.

Reports of Societies.

MEDICAL SOCIETY OF VIRGINIA.

Fifteenth Annual Session, held at Rawley Springs, Va., September 9, 10, and 11, 1884.

(Special Report for The Medical Record.)

Tuesday, September 9th—First Day.

The fifteenth annual session of the Medical Society of Virginia convened in the main room of the hotel at Rawley Springs, Rockingham County, Va., at eight o'clock on Tuesday evening, September 9th, the President, Dr. J. Edgar Chancellor, of Charlottesville, in the chair.

The meeting was opened with prayer by Rev. Dr. Robert C. Mattlack, of Philadelphia.

Dr. M. G. Ellzey, of Washington, D. C., in behalf of the management of the Springs, delivered an address of welcome, in the course of which he warmly greeted the delegates, and referred to the fact that the doctors of Virginia could better recommend to their patients the mineral waters of the State after personal inspection of them at the native springs.

Dr. J. E. Chancellor, President, for the Society, made a few appropriate remarks in reply, and in behalf of the members present thanked the Springs management for the hospitable welcome they had already received.

Dr. Robert I. Hicks, of Fauquier County, then read the address to the public and the profession, entitled

HYGIENE IN RELATION TO THE PRIVATE FAMILY.

He began by showing the important relations existing between individual sanitation and the public health. He briefly described the investigations of Pasteur, Koch, and Devaine, in connection with the germ theory, explaining the microbes, bacilli vibrios, and spores found by these observers in different forms of disease, and warned his hearers not to be too ready of belief as to these micro-organisms producing disease, as they may be simply accompanying the disorders in question. After this question is fairly settled, there yet remains the most important thing to be done, *i.e.*, how to best destroy them. He enumerated the different hiding-places of these germs, and showed that by destroying the conditions that make and support them we can in that way do best in practical hygiene. He said that while these agents do exist, and their existence is as yet unavoidable, it is a further fact that we are responsible for them to a much greater extent than we are willing to admit. Many are chargeable to ignorance and recklessness. He showed how some of the preventable diseases are produced simply from people not having a knowledge of the primitive points of practical hygiene. Public legislation, while in every way desirable, can do little else than establish general quarantine laws against the great plagues, but, except in a general way, it cannot enter into the private house, it cannot reform the domestic habits, it cannot enforce purity in a private well, and as these things involve the life and health of the family, they must be attended to from within. As nations are but aggregations of individuals, as is the individual so is the nation. Toulon and Marseilles are now paying the terrible penalty of individual uncleanliness.

The happiness, longevity, and often the success itself of man, is largely dependent upon an intelligent recognition of the laws of health. Misery, disease, and failure in life are the penalties paid for their violation. Penalties extending beyond one generation are frequently the result of personal neglect. Our present knowledge of pathology shows us that diseases are often perverted life processes, and are therefore more easily prevented than stamped out when once begun.

Dr. Hicks showed a firm belief in the preventability of consumption, and did not think it hereditary to anything like the commonly accepted extent. Out of one hundred cases in New York only twenty-six per cent. were hereditary, the remainder (seventy-four per cent.) are charged to damp air, insufficient food, poverty, and filth. He wished to impress upon his hearers the fact that tubercle is not a new formation dependent upon hereditary taint, but is merely an alteration of normal nutrition, a degraded tissue resulting from neglect of trivial complaints in connection with a disregard of ordinary sanitation. He illustrated these and other points by cases drawn from his private practice. He classed Bright's disease, dyspepsia, gout, etc., as preventable diseases, due frequently to personal habits. No organ can continue sound and be the constant carrier of morbid products. The remedy for this class of complaints consists in change of habits, moderation, etc. The subject of the location of the family house and its bearing upon the health of its inmates was taken up and carefully discussed, the point being also illustrated by cases under his own observation. He pronounced pure air antiseptic, showing, by well-chosen illustrations, its influence on animal life. He thought that from 1,200 to 2,000 cubic feet of air must pass through a room every two or three hours to make it healthy for one individual. The addition of one other person impairs its purity and renders it unfit for use. It becomes not only unhealthy but unclean. He took up the subject of ventilation, and gave some practical hints regarding it. He called the attention of his hearers to the fact that dry heat was the only perfect disinfectant, extreme cold having failed in that direction in many instances. The importance of light, both to the well and sick, was touched upon, and practical examples were given from his own observation. He then showed, from cases in his own practice, how typhoid fever, diphtheria, and some other diseases were often caused by the presence of old rubbish, bad water, and filth. He believed that certainly in decaying animal matter, and probably also in decaying vegetable matter, are found the germs that produce zymotic diseases. The thorough destruction of these matters insures the destruction of the germs. As one person, by bad personal habits, may not only produce disease in himself but pass it on to others, the innocent suffering with the guilty, each individual should feel the great responsibility resting upon himself. He concluded by showing the economical side of the sanitary question, proving how much could be saved by personal attention to the first principles of hygiene, and demanded a higher grade of education for the children of to-day in matters pertaining to individual and home sanitation.

At the conclusion of Dr. Hicks' address the Secretary read the names of forty-four physicians who applied for admission into the Society. By vote the list was referred to the proper committee.

THE SERIOUS ILLNESS OF HONORARY FELLOW DR. R. S. PAYNE,

of Lynchburg, having been announced by a member, the Secretary was directed to telegraph to him the

resolutions of sympathy adopted by the unanimous vote of the Society.

The nomination and election of officers of the Association were then taken up.

The evening session was devoted to a consideration of

THE PHYSICIANS TO BE APPOINTED UPON THE BOARD OF MEDICAL EXAMINERS.

The State is divided into ten congressional districts and the bill provides that the State Medical Society shall nominate three men from each district, and two from the State at large. These names will be presented to the Governor, and, if satisfactory to him, the physicians named will constitute a Board for the examination of every doctor who desires to practise medicine in Virginia after January 1, 1885. The following named gentlemen were selected by the Society as

EXAMINERS.

From the State at large—Drs. William C. Dabney, of Charlottesville, and F. D. Cunningham, of Richmond, were unanimously elected. First Congressional district—Drs. W. W. Douglas, of Richmond County, O. B. Finney, of Accomac County, and S. W. Carmichael, of Spottsylvania County. Second district—Drs. Thomas B. Ward, of Norfolk, L. Lankfold, of Southampton County, and Jesse H. Peek, of Hampton. Third district—Drs. R. Lewis, of Richmond, C. R. Cullen, of Hanover County, and O. Crenshaw, of Richmond. Fourth district—Drs. Hugh Stockdell and J. H. Claiborne, of Petersburg, and Dr. William J. Harris, of Black's and White's, Nottaway County. Fifth district—Drs. Rawley Martin, of Pittsylvania County, William L. Robinson, of Danville, and T. B. Greer, of Franklin County. Sixth district—Drs. H. Gray Latham, of Lynchburg, Harvey Black, of Blacksburg, and Oscar Wiley, of Roanoke County. Seventh district—Drs. William P. McGuire, of Winchester, J. H. Neff, of Rockingham County, and Hugh T. Nelson, of Albemarle County. Eighth district—Drs. Alexander Harris, of Jeffersonton, C. C. Conway, of Orange County, and Bedford Brown, of Alexandria. Ninth district—Drs. S. W. Dickinson and R. D. Huffard, of Smyth County, and Robert J. Preston, of Washington County. Tenth district—Drs. Merriwether, of Amherst County, Z. G. Walker, of Rockbridge County, and H. Patterson, of Highland County.

WEDNESDAY, SEPTEMBER 10TH—SECOND DAY.

DR. WILLIAM C. DABNEY, of Charlottesville, as chairman, read the

REPORT OF THE COMMITTEE ON MEDICAL LEGISLATION,

in the course of which he referred to the work done during the meetings of the Legislature in the past few years, closing with showing the success the committee met with in the last legislature, an act providing for a Board of Medical Examiners having been then passed. Although the bill finally passed was not exactly what the profession desired, still it was far in advance of no act at all for the protection of the people of the State. The committee was discharged with the full thanks of the Society.

DR. L. B. EDWARDS, of Richmond, then read for DR. H. T. NELSON, of Charlottesville, the report on

ADVANCES IN ANATOMY AND PHYSIOLOGY,

and after making excellent references to what had been done in this line in the past few years, he began his report by showing the newer discovered morphological components of the blood, and referred to the late examinations of this fluid made by German and Italian scientists, mentioning their beliefs in thrombosis, etc.

The next subject taken up was the physiology of digestion, and the writer spoke of the newer theories concerning peptones. All the tissues of the body contain some digestive power, according to one observer. Albumen and peptone are identical, if we are to believe some authorities. According to Dr. Frank, of New York, animals fed on peptones were nourished in the same manner as if fed on albumen. The favorable views of Dr. Jacobi on peptone feeding were quoted with great praise. The subject of the intracranial nerve-system was taken up, and the writer confined his remarks mainly to the sensory portion of the encephalon, taking occasion to remark that there had not recently appeared any additions to our existing knowledge of the cerebral motor centres and their connections. He closed by expressing the hope that his paper might have some practical bearing upon alimentation in disease, and might encourage more general study of cerebral pathology, a more perfect knowledge of which must ultimately increase the longevity of our race.

THE PRESIDENT, Dr. J. E. CHANCELLOR, then delivered his annual address, taking as his subject

A BRIEF REVIEW OF THE ORIGIN AND HISTORY OF MEDICINE.

After a few introductory remarks he began by congratulating the Society upon the great and growing interest so evidently manifested in the yearly meetings, as evidenced by the large attendance last year, and the still larger attendance of members this year, about one hundred and twenty-five being present. The character of the papers presented had also improved of late years. He mentioned especially the great work done by the Society members, in securing, since the last session, a partial recognition of the rights of the profession, by Legislative enactment, in the passage of the Anatomy Bill and the act establishing a State Board of Medical Examiners, but also said that, gratifying as this fact may be, there yet remains much to be done by the proper authorities. With his words of greeting he said was mingled the always sad duty of presenting to the Society the tidings of the work of death among the membership during the past year. It had seemed to have been a year of unusual mortality, among the elder members especially. Six or eight of the charter members have died since the last meeting, and several of the younger Fellows. Three of those taken from the Society's work were ex-presidents, and one a distinguished professor in the Medical College of Virginia. The speaker paid a brief tribute to the memories of the departed members, and referred in touching terms to the memory of our beloved Honorary Fellow, Dr. J. Marion Sims, calling him the Moses of our profession, as well as the father of gynecology in America.

He then passed to the consideration of his subject proper, saying that the central and all-absorbing thought of the world of medicine was *progress—scientific progress*, the development of a more advanced medical education, and a higher standard for graduation. The advance in medical science has been so rapid, and the glamour thrown around the medical study of to-day was so great, that there was danger that the work in its development done by the earlier fathers of medicine would be overlooked. He would like to call a halt in this, and ask the members present to review with him briefly the origin and history of ancient medicine. He then proceeded from his standpoint to show that with the creation of our first ancestors the necessity for the healing art originated, and he proceeded to unfold, step by step with the progress of ages, its growth into a science. He first took up the medicine of the patriarchs, following it up through centuries to the sacerdotal system or that of the priesthood, and in what manner these had led to the present distinctly professional system. He plainly showed that medicine had an organized existence nine hundred years before Hippocrates—the generally accepted "Father of Medicine"—and perhaps even beyond this. He quoted Herodotus to show the expedients commonly re-

sorted to in the earlier days of science, the recording of cases treated, and remedies used, by writing on the walls of ancient temples, etc. The president then went on to describe the systems of medicine. He began with the Ayar Veda, or sacred revelations of the Hindoo system, and then spoke of the Greek system, fully elaborating the subject. The Roman and Israelitish systems of medicine were fully brought into review, and the entire portion of the paper relating to these systems showed great research and much familiarity with the matters referred to. He also gave an interesting account of the Ebus papyrus, found at ancient Memphis about ten years ago. He referred to this "hermetic book of medicament" now to be seen at Leipsic, and said that it showed diagnoses made, remedies suggested, and systematic treatment of diseases about 1600 B.C. He then traced the origin and progress of medicine in Egypt, and how in after years it was first introduced into Rome, bringing it down to the time of Hippocrates. He spoke of the origin of the medical school at Alexandria and those of Cridnos, which gave rise to the Cridnerian lectures, etc. After this he took up the history of those men who were most prominent under the different systems of the practice of medicine in the olden time.

He referred to the importance of properly organizing and of selecting the proper men who should be placed upon the Board of Medical Examiners for the State, to be appointed during the session, urging the society members to make it a thoroughly independent body. He, although praising the work of the committee, did not by any means look upon the act constituting a Board of Examiners as it now stands, to be exactly what the profession desired, and suggested the appointment of a committee to recommend amendments to the bill as seemed necessary. He took up the subject of the State Board of Health, and showed how ridiculous such a board was made by the fact that no money is given it by the State to do any work with, it consequently being without efficiency, and in fact a nullity. Lastly, he urged that steps should be taken to secure, as soon as possible, a full history of the deceased medical men of the State of Virginia, as it certainly was the duty of the present generation to rescue from oblivion the galaxy of illustrious names which have been emblazoned upon the honorable page of medicine in Virginia.

THURSDAY, SEPTEMBER 11TH—THIRD DAY.

The morning session opened at 9.30 o'clock, Thursday, and the regular business of the Society was proceeded with. After the reading of letters from non-resident honorary fellows, etc., and work of like nature, DR. J. M. TONER, of Washington, was unanimously elected an honorary fellow of the Society.

DR. S. B MORRISON, of Rockbridge County, presented resolutions of

RESPECT TO THE MEMORY OF DR. J. MARION SIMS,

one of the most prominent fellows, which were unanimously adopted by a rising vote.

Dr. S. B. Morrison then read his report on

ADVANCES IN OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN.

He began by running over the case of pregnant women, and not only referred to the familiar truths of obstetrics, but from his own practice illustrated many of his points. He protested against too much interference with the physiological process of child-bearing, and thought that, as a rule, the less duty the accoucheur felt called upon to perform the better for the patient. He instanced the ease with which the Indians of this country went through this most natural work. He referred to the use and abuse of ergot and chloroform, and fully mentioned the proper method of employing massage and expression. Forceps, he thought, were invaluable, and he pronounced decidedly in favor of the use of the instrument. He believed fully in Denman's rule, that when the ear of the child can be plainly felt in the lower strait the forceps should be employed. Uterine hæmatocele in pregnant women was touched upon, and the reader presented a case from his own practice illustrative of this condition. He referred to the common occurrence of gynecological disorders, and in reporting some of his own cases illustrated the points made in his paper.

He particularly made reference to the fact that an early treatment should be employed in instances of the kind, and laid down the rules he was in the habit of adopting in like cases. Battey's operation he thought would not stand the test of time. He was very desirous that a school for nurses should be established in Virginia. On conclusion of the paper, several members made a few remarks concerning the views presented.

DR. JOHN CLOPTON, of Williamsburg, presented, through another member, his paper upon

ADVANCES IN PSYCHOLOGY AND NEUROLOGY,

which was simply an apology for not preparing a full report.

DR. GEORGE D. HARRISON, of New York, by invitation, read a paper upon

THE MODERN TREATMENT OF WOUNDS.

He considered the subject very fully, detailing the work of micro-organisms on the living tissue. He made a clear statement of the necessary procedure to produce an antiseptic condition of wounds which had taken on suppurative action. His method in operations was, first to keep the wound in an aseptic condition until the dressings were applied, and second, to put on the dressings in such a manner that the wound will remain aseptic. He detailed all the processes of cleanliness which were to be employed in such instances; how the instruments, sponges, operator's hands, drainage-tubes, sutures, etc., should be treated to render them aseptic. Lister's full dressing was described. He was favorably inclined toward the use of iodoform. He said that, according to Von Minewarter, the healing process after the use of the Lister method was decidedly shorter in point of time, and that he fully believed in the same mode. He thought the day of that terrible bugbear of surgery, septicæmia, was about past, and that if operators would fully adopt the *clean method* of treating wounds favorable results would be more frequent. He concluded by paying an eloquent tribute to those men of great scientific renown, Pasteur and Lister.

DR. HUNTER MCGUIRE made some practical remarks upon wounds and their treatment, and gave most excellent advice concerning cleanliness in operations in private practice.

Dr. G. S. Stone, of Loudon County, Dr. S. B. Morrison, of Rockbridge County, Dr. J. H. Neff, of Harrisonburg, Dr. Wm. L. Robinson, of Danville, Dr. J. E. Chancellor, of Charlottesville, Dr. L. Lankford, of Southampton County, Dr. Alban S. Payne, of Atlanta, Ga., Dr. R. Tatum, of Harrisonburg, Dr. Jessie Ewell, Sr., of Prince William County, and Dr. H. M. Patterson, of Highland County, discussed the subject.

The next paper read was presented by DR. ALEXANDER HARRIS, of Jeffersonton, Va., on

THE MEDICINAL PROPERTIES AND THERAPEUTIC APPLICATION OF THE WATERS OF FAUQUIER WHITE SULPHUR SPRINGS, VA.

The reader purposed to give a careful and rational explanation of the medicinal properties and therapeutic application of this water through its chemical constitution. The springs being at such an elevation—about seven hundred feet above sea level—the hygienic surroundings of the hotel and grounds are unsurpassed, this being plainly evidenced by the fact that the writer has not been called upon to treat a case of zymotic disease which had its origin on the premises during his thirty-five

years' connection with the springs. The water is remarkable for its lightness and possesses a very strong sulphurous taste and smell. The quality of lightness enables the patients residing at the springs to ingest nearly twice as much in quantity than if it were an ordinary freestone water. The experience of Dr. Harris and others has shown the water to be primarily diuretic, diaphoretic, or purgative, and secondarily alterative and tonic. It gives, when first tasted, a perceptible stimulant effect, in some cases causing a sense of fulness of the head, in some few cases going so far as to produce headache. The reason for the remarkable therapeutic properties possessed by this water can be readily seen by a careful examination of an analysis of it. There are nearly three grains of iron phosphate, lime, and magnesia in the gallon, and it can be understood how the tired brain is rested and the overworked nervous system is built up by the use of these waters. The reader then compared the analysis of this water with the analyses of 178 of the most important and best known natural mineral waters of this country and Europe, and showed how rarely the ferric phosphates were to be found in those waters—there being only two of this number which have any of this salt in solution, namely, the water under discussion (containing two grains to the gallon), and the Newbury (two-fifths of a grain per gallon). It can be readily understood how broad a range of therapeutic application the Fauquier White Sulphur waters possess in those cases of chronic diseased action dependent upon loss of nerve-power. Not only did Dr. Harris draw upon his own record of practice for illustrative cases, but referred to Burke's work on the Virginia Springs for a number of instances where these waters had done so much good. The use of this water, according to Dr. Harris, is especially valuable in dyspepsias of neurotic origin, in dropsies, in certain instances of neurasthenia, etc.

The third day's afternoon session began at three o'clock Thursday, 11th inst., with the report of Dr. H. W. Clarkson, as chairman of the delegation from the Society to the last session of the American Medical Association.

The committee appointed to report upon the

THERAPEUTIC VALUE OF RAWLEY SPRINGS WATER,

made a return through the chairman, Dr. T. M. Miller, of Frederick County. In his paper he entered into a full analysis of the water, and compared it with that of the most noted and best visited springs of this and other countries. The especial point in Rawley water which renders its therapeutic properties so valuable is the large quantity of protoxide of iron placed in complete solution by the excess of carbonic acid contained therein. The iron being rapidly appropriated by the red corpuscles of the blood, the anæmic patient who uses the water is soon put into a condition where proper assimilation takes place. The water abounds in carbonates, not only of iron, but also of all the common alkalies to the exclusion of the sulphate.

Dr. F. M. Robertson, of Charleston, S. C., by invitation of the Society, also read a paper upon the same subject, the medicinal virtues of Rawley Springs water, in the course of which he very highly extolled its effects.

Drs. George Harrison, of New York City, and F. M. Robertson, of Charleston, S. C., by unanimous vote of the Society, were made non-resident Honorary Fellows.

Dr. Chancellor then yielded the chair to his successor, Dr. S. K. Jackson, of Norfolk, and was unanimously elected an Honorary Fellow of the Society.

The following summer resorts extended invitations to the Society to hold its session of 1885 at their hotels; Rawley Springs, of Rockingham County; Alleghany Springs, of Montgomery County.

It was decided by vote to meet at Alleghany Springs in the fall of 1885.

A unanimous vote of thanks for the extreme kindness and hospitality extended this year to the Society by the Rawley Springs management was passed, the management entertaining the members free of all hotel charge during the session.

Dr. Hunter McGuire then presented his paper upon

INTESTINAL OBSTRUCTION—ITS DIFFERENTIAL DIAGNOSIS.

He began by relating some illustrative cases, which showed the necessity of making, as far as possible, an early and positive diagnosis, for the purpose of operating if necessary. Yet he had seen patients recover entirely with but little or no treatment. He gave the different modes of production of this condition, and showed how operative treatment often offered great prospect of recovery. The paper was mainly confined to the diagnosis of this difficulty. He had seen a patient die in thirty-six hours, and had also seen others which recovered thoroughly after a complete condition of obstruction. He laid down, as a rule, the fact that no purgative should be given at first. This he considered one of the most important points to be remembered. He looked upon opium as the sheet-anchor in these cases. He criticised most unfavorably several of the older methods of treatment. He showed when he thought was the proper time for opening the abdomen, namely in certain cases, in thirty-six hours after the proper medicinal treatment had been faithfully tried.

ETHERIZATION BY THE RECTUM.

Dr. William H. Coggeshall, of Richmond, Va., then read a paper upon this subject, and showed that the method was by no means a new advance in therapeutics, but simply a revival of the process of Pirogoff, who employed it in 1848, a year after the discovery of ether anæsthesia. The writer traced the employment of the rectal process down to about thirty years ago and showed that no clinical record had been made of its use since then, until M. Mollière wrote his first paper for the *Lyons Médicale*, in March last, explaining that Dr. Axel Iversen, of Copenhagen, had called his attention to it, and referred to six successful cases by this method. Dr. Coggeshall presented the details of fifty cases where rectal anæsthesia had been employed, this number being all he could find fully detailed in the American medical journals of this year, one or two occurring in his own practice. He found from examination of the cases reported that by this process the preliminary stage of excitement in anæsthesia is certainly of shorter duration than when the vapor is inhaled. There is also less vomiting, but it may occur at an unexpected time during the operation. The question as to whether the return to sensibility after this method is quicker than when inhalation is used he thought to be doubtful. The great element of danger, however, and the reason why rectal etherization will never come into general use, is because of the liability of the mucous membrane of the lower bowel to take on inflammatory action from the presence of the ether vapor. Two fatal cases were given by the writer out of the fifty reported, making four per cent. of deaths. He gave the fullest instructions for the employment of this method when it was required, as in face and mouth operations, and described his own form of home-made apparatus for rectal anæsthesia, which could easily be improvised by any doctor even away from the city. The several important points insisted upon for the use of ether vapor per rectum were as follows: The lower bowel should be thoroughly cleansed by enemata before the introduction of the rectal tube; the connecting-joints of the tube and tubing must be perfect; the tubing should be about two feet long; the water-bath should be kept as nearly as possible at the same temperature—120° to 140° F.; the rectal tube should be withdrawn when insensibility is complete; the nates should be held tightly together by an assistant; the possibility of sudden peristalsis occurring during the operation should be provided for. The doctor concluded by advising only those to experiment with this method who could afford to take some risk.

The Society by vote thanked Dr. Coggeshall for his painstaking collection of cases of this method.

Dr. William G. Rogers, of Charlottesville, then, as chairman, read the report of the committee appointed last session to secure legislation against the practice of druggists refilling prescriptions containing narcotic poisons without the renewal order by a physician. Although the Committee worked hard for it the bill was not passed by the Legislature last winter.

The evening session opened at 7.30 o'clock, Dr. Samuel K. Jackson, President, in the Chair, with the reading of an excellent paper by Dr. M. A. Rust, of Richmond, on

TYPHOID FEVER.

The reader went rapidly over the pathology of the disease, showing the tissue changes he believed to occur. He spent some time in defining this particular fever, and made a strong protest against calling the fever which is now, and has been, endemic in Richmond, a form of "typho-malarial fever," as he thought that such a combination did not exist. He looked upon it as a special grade of enteric fever, which might be called a by-name for typhoid. He thought the special germs producing malarial fever and typhoid fever never became blended in any one case—in fact that it was impossible for such blending to occur. He endeavored to show that typhoid fever was a distinctly defined disease, whether severe or light in character, having a truly personal character of itself which could never be mingled with that of any other. His treatment for this disorder was mainly cold sponge bathing, sulphate of quinia, bismuth, beef-tea, and wine, and he had great faith in milk as the main article of diet. He recommended that the milk be always boiled for use.

Dr. Alban S. Payne, of Atlanta, Ga., non-resident Honorary Fellow, next read a paper on

CEREBRO-SPINAL MENINGITIS.

He began by saying that as he had so often met with cases of cholera morbus and cholera infantum which could not be differentiated from cerebro-spinal meningitis, he would make a few remarks upon the disease known as cholera infantum. His remarks concerning meningitis were very apt, and were attentively listened to by the members. He had found the monobromide of camphor to be very valuable in treating these diseases. He blisters the nape of the neck with croton-oil, and usually gives a hot mustard bath. Quinine should be given at night or morning, and he was in the habit of giving chlor-anodyne to control pain.

Dr. I. S. Stone, of Loudon County, then read a paper upon the use of

MASSAGE AND ELECTRICITY IN HYSTERIA AND ALLIED DISORDERS,

from the point of view of the general practitioner. He went over some of the forms of hysteria and neurasthenia, and related his success in several such cases. He was a firm believer in the theory and practice of Dr. Weir Mitchell, and thought he had in several instances improved in some degree the methods adopted by that celebrated specialist. He showed how the ordinary country practitioner could successfully handle this class of cases, and illustrated the points mentioned by two or three very severe cases of nervous disease. Seclusion, he thought, was one of the best helps in treatment, especially in female patients, as the constant attendance of visitors to see and talk with the patient that "has such strange symptoms and so bothers the doctors," certainly does an enormous amount of injury. He believed in the value of a skim-milk diet in these cases, and he also used quantities of raw beef made into a broth, after the method of Weir Mitchell.

At 10.30 o'clock the Society was invited by the Rawley Springs management to a very handsome complimentary banquet. The embossed *menus* were engraved and printed for this special occasion, the tables were decorated with flowers, etc., and the wines were excellent. It was a remarkable affair to have been gotten up, off in the country, eleven miles from the railroad.

FRIDAY, SEPTEMBER 12TH—FOURTH DAY.

The fourth day's session convened at 9.30, Friday morning, by Dr. J. N. Upshur opening the discussion on

MALARIAL FEVER,

by reading a paper prepared on the subject by Dr. R. B. Storer, of Richmond. The writer began with a history of miasma, presenting, up to the present year, all that is known on this branch of the subject. He then went into the causation of this condition, and referred especially to the fact that in Richmond, for the past ten years, whenever the streets have been torn up for the purpose of putting in new culverts, etc., fever has invariably followed the excavations. He also mentioned the fact that in that city there are certain portions where fever has followed the introduction of water from a certain part of the water-supply canal, when the other districts of the city have been entirely free from it. He showed that this was the case even where chemical analysis and microscopical examination failed utterly to show anything wrong with the water.

Dr. J. N. Upshur, of Richmond, then presented a paper on

MALARIAL FEVER AS IT OCCURRED IN RICHMOND IN THE SPRING AND SUMMER OF 1884.

He called special attention to the fact that fever of this type occurred generally in other parts of Virginia as well as in Richmond. The type of fever presented some peculiarities different from that ordinarily seen. No doubt the cause of the fever was entirely atmospheric. It will be remembered by the local profession that there was a great deal of rain during the spring and early summer. The reader had noticed on several occasions at night, and it was remarked by others, that there was a most peculiar odor in various parts of the city. It is manifest that the water could have been *no element* in the production of the fever, for the reason that if it had contained the germs of infection, the disease would have attacked all ages and all parts of the city alike, there being little difference in the constitution of the water whether it comes from the canal, or the river, or from the old or new reservoir. The subjects of the fever were mainly young people. Another fact: the fever prevailed in other parts of the State where the inhabitants, it may be inferred, drank well-water, and not James River water. The march of influenza and epizootic disease is an analogous fact. The disorder prevailed from the first of May to the middle of June. The malarial influence during the present summer has been apparent in all the prevalent acute diseases. The doctor draws strong conclusions from the analysis of the drinking-water by Dr. Wm. H. Taylor, State analyst, which has been recently published in the Richmond newspapers. Finally, all of the conditions of the weather were favorable to the production of a malarial disease. An interesting feature of the fever was the coolness of surface when the thermometer indicated a high range of temperature. The doctor reports several cases as illustrative of the features of the fever, one of which is of special interest from the fact that, neither the mouth nor bowel being available at the period of greatest prostration, the patient was kept up by systematic stimulation by means of the subcutaneous injection of brandy. This patient recovered. Dr. Upshur also called especial attention to the presence of epigastric pain as a symptom diagnostic of malaria in children.

Dr. William L. Robinson, of Danville, then read a paper upon

TYPHO-MALARIAL FEVER

as it has occurred in his section of the State during the past ten or twelve years. He presented the symptoms of the fever, and showed that he was correct in describing it as peculiar. It seemed to differ from the same

class of disorder occurring in other sections, and demanded a different form of therapeutic application from that commonly employed. The writer thought that quinine was given too often in large doses in this condition, and remarked that he had never had an abscess from the use of this salt when employed hypodermically, although he frequently gave it in this manner.

Dr. Thomas J. Moore, of Richmond, then delivered a short and practical speech on the general points involved in the causation, diagnosis, and treatment of

MALARIAL FEVER.

He showed that no spot was safe from the attacks of this disease, and that wherever heat, moisture, and decaying vegetation existed it would almost invariably be found. He spoke of the value of drainage, and that malaria could be driven away mile by mile by a proper system of the kind. He gave his personal experience in cases of malarial hæmaturia which he had so frequently met with in North Carolina. He rapidly went over the different conditions under which this disease (malaria) was usually found, showing the varying types. He recommended as treatment for malarial fever what had been empirically found best adapted for this condition in each certain section, except that, early and always, quinine should, of course, be employed. He decidedly preferred to administer the salt hypodermically, and thought that abscesses would be less frequently met with if the needle was boldly pushed into the cellular tissue, and the solution not thrown into the skin. He gave some excellent advice about how to make up the solution, so that the quinia should not only be perfectly dissolved, but that the liquid should not have an acid reaction. He was also impressed very favorably with the action of Warburg's tincture. In connection with the hypodermic injection of quinia, he had found that the addition of a small dose of morphia to each injection was of great value in certain conditions of malaria.

The speaker spoke directly to the point and was listened to with the closest attention.

The President, Dr. S. K. Jackson, made a few remarks upon some of the points raised, and especially recommended the milk diet in typhoid fever. He was absolutely opposed to all starchy foods. He had at times, when using maltine, been able to allow the patient to take a little of that class of food. He made great use of strong beef-tea, and usually kept the patient on nothing but the latter liquid and milk through the course of the illness.

Drs. Stone, Moore, Upshur, and Rust discussed the subject of malaria, but no novel views were presented. A great difference of opinion was manifest regarding the question as to whether typho-malarial fever was a distinct disease.

A paper by Dr. E. E. Field, of Norfolk, entitled

YELLOW CHILLS,

was read by title.

Dr. William Selden, of Norfolk, was elected an Honorary Fellow of the Society, and a considerable amount of routine business was transacted.

Dr. Joseph A. White, of Richmond, then presented a paper entitled

SOME REMARKS ABOUT CATARACT, WITH A REPORT OF FIFTY-TWO CASES.

After speaking of the mistakes often made in confounding other eye troubles with cataract, by careless practitioners, some of which are ludicrous and some serious in their tragical results, he gave a short history of the operation of "extraction" with the various modifications it has undergone. He advocated strongly the performance of iridectomy as increasing the chances of a successful result, in opposition to the recent tendency of the French school to return to Daniel's method, also showing its advantages as a preliminary operation in certain cases, as it divides and diminishes the traumatism. He gave an account of Foster's operation of "trituration of the lens" for ripening cataract, with a reference to some cases of his own, but considered that it has, like all other surgical operations, its attendant risks, and is as yet only on probation. After some remarks on the opening of the capsule, he passed to a consideration of the cases operated on in Richmond during the past four and a half years—fifty-two in number. There were no failures in cases under seventy years of age, and only two over seventy years, as a result of the traumatism. Another patient lost his eye after recovery, from septic infection of both eyes, by a sponge used by a hospital attendant, setting up purulent ophthalmia. Anæsthesia was used in eleven cases only, and the most serious accidents during the operation, which occurred in nine cases, he attributed to the vomiting induced by the anæsthetic. He uses anæsthesia only in very timid or cowardly patients, because there is very little pain from the operation if he can trust to the statements of those operated upon. In regard to antisepsis in cataract operations, he thinks that it is quite sufficient to see that the most scrupulous cleanliness before and during the operation is observed, especially of all the instruments employed. He uses instruments as little as possible, and after the iridectomy does away with the blepharostat and uses the lids and his fingers to remove the lens. In regard to the secondary operation of cutting the capsule he considered it of great importance as increasing the visual acuteness and lessening the chances of subsequent reaction about the capsule and iris, and instanced a case in point where, from neglect of this precaution, a patient with good vision lost the eye eighteen months after, the trouble starting in the capsule, which had gradually thickened and wrinkled, ending in iridocapsulitis and cyclitis. Dr. White concluded his paper with a full report of a case of some physiological interest as exemplifying the accepted theory of vision. A man named Daniel F——, of Weldon, N. C., had become blind with double cataract when seven years of age, was educated in an asylum for the blind, and was operated on in Richmond, Va., when thirty-two years old. The result was perfect vision in both eyes. He could judge nothing of the shape of an article until he touched it. He could not locate objects in space, and invariably miscalculated the distance when reaching for anything. He was afraid to walk about because he could not judge of the height or depth of anything in his way—such as gutters or curbstones. In fact he was less independent when he first recovered vision than before he was operated upon.

It was decided that the subject of "Scarlet Fever" should be the one for general discussion at next year's meeting, and Dr. Thomas J. Moore, of Richmond, was appointed to read the first paper on the subject.

The Society then adjourned *sine die*.

Altogether the session of 1884 was the best one ever held by the Society, the papers read were in the main valuable and practical, the attendance the largest in the history of the Association, there being between 125 and 250 members registered as present, and over sixty new members were elected.

The following are

THE OFFICERS ELECTED FOR 1884–85:

President—Dr. Samuel K. Jackson, of Norfolk; *First Vice-President*—Dr. Jesse Ewell, Sr., of Hickory Grove, Prince William County; *Second Vice-President*—Dr. Benjamin Blackford, of Lynchburg; *Third Vice-President*—Dr. Robert I. Hicks, of Casanova, Fauquier County; *Recording Secretary*—Dr. Landon B. Edwards, of Richmond, Va.; *Corresponding Secretary*—Dr. Hugh Taylor, of Richmond, Va.; *Treasurer*—Dr. Richard T. Styll, of Richmond, Va.; *Executive Committee*—Dr. W. W. Parker, of Richmond (Chairman), Drs. Harvey Black, Francis D. Cunningham, John Herbert Claiborne, and L. Ashton; *Committee on Publication*—Drs. E. T. Robinson, C. W. P. Brock, and George Ross.

International Medical Congress.

EIGHTH SESSION.

Held at Copenhagen, Denmark, August 10–16, 1884.

REPORTS OF SECTIONS.

SECTION OF OBSTETRICS AND GYNECOLOGY.

Prof. Koeberlé, of Strasburg, read a paper on the

TREATMENT OF UTERINE MYOMATA BY LAPAROTOMY.

The indications for the operation were: the gravity of the state of the patient in consequence of excessive or prolonged catamenial hemorrhage, or from the rapid or continued increase of the tumor, and from the age of the patient, from the seat of the tumor, by the particular circumstances, as when life became unsupportable from the troubles caused by the tumor. Operation was contra-indicated when there were extensive vascular adhesions to the abdominal walls, or when the too extended tumor had too extensive connections; when it was enclosed in the pelvis; when there was ascitic effusions liable to increase, and to reproduce them quickly; or when there was some concomitant incurable affection, or some circumstances which might exercise an unfavorable influence in recovery. The operative method varied according to the seat and size of the tumor. Uterine fibro-myomata should be operated on by the vaginal method in cases where they formed a more or less pronounced swelling in the uterine cavity and toward the vagina, when the size of the canal thus allowed extraction in this way. Fibro-myoma, projecting into the extreme cavity, and immovable by the genital canal, as well as interstitial and sub-peritoneal tumors were capable of removal by laparotomy. Professor Koeberlé spoke on hysterotomy and hysterectomy, and gave the general rules for their operation. He stated the result was very favorable when the tumors were developed in the body of the uterus. The operation was difficult and grave when the tumors were developed in the broad ligaments, and deeply imbedded in the pelvic cavity. The reunion of the abdominal wound, dressing, and antiseptic treatment were next passed in review. Dr. Koeberlé concluded his paper by affirming that the treatment of uterine fibro-myomata by laparotomy constituted a real progress in contemporary surgery, and merited in every way serious considerations.

This communication was well received and discussed by Sir Spencer Wells, of London, Dr. Margary, of Turin, and Dr. Apostoli, of Paris.

ELECTRIC TREATMENT OF UTERINE MYOMATA.

Dr. Apostoli, of Paris, proposed a new electrical therapeusis for uterine fibromata, distinguished by its point of application, nature, intensity, and its manual mode of application. To the old procedure of the application of continuous currents to the cure of fibrous tumors—characterized: (1) by very feeble electrical intensity; (2) by the vagina being oftenest the point of application of the positive pole—he opposed a treatment always more active, since it reached 100 millimetres of intensity, and was always intra-uterine, acting along the whole depth and extent of the uterine mucous membrane. A clinical experience, extending over two years, upon over one hundred cases, had shown that the treatment constantly reduced the size of the uterus, and completely restored the patient.

DESTRUCTION OF UTERINE TUMORS BY ELECTROLYTIC PUNCTURE.

Dr. P. Menière, of Paris, advocated the destruction of uterine tumors by electrolytic puncture. This, he said, constituted an operation which was effectual and of little danger, provided that it were practised, not by the vagina, but across the abdominal wall. It was indicated —(1) when medical treatment had failed; (2) where the fibromas were very large, and also only slightly movable; (3) when they endangered the life of the patient by continuous metrorrhagias or grave general trouble; (4) it was a final resource in cases where total removal was impossible. This operation had already been practised by Cutler in 1871, Broure in 1873, Kimbal in 1874, Cinisalli in 1875, and Semeleder in 1876. But their operative procedures differed, were very vaguely described, and little known in Europe. In face of the marvellous results which he had got in six cases, the results of which were indelibly fixed in his memory, it seemed to him to be of interest and useful to call the attention of the Congress to this point of gynecological therapeutics, and particularly to the manual method of procedure, on which he had, after numerous trials, finally settled. The instruments employed were: (1) a battery of the continuous current of Gaiffe, with twenty-four pairs of zinc plates, and galvanometer divided in milliampéres; (2 gold needles, ten centimetres long by a millimetre and a half thick, flattened and pointed at their extremities (o lance-shape, with cutting edges); they were isolated for a length of seven centimetres by means of resinous varnish, dried and calcined in the flame of a spirit-lamp (3) a needle propeller, with a graduated stop-notch, so as to insert the needles to a depth previously fixed upon; (4) light and flexible conducting wires, joined to the needles by means of a *serres fines*. The operation was, he said, repeated twice a week, or every ten days, in case of inflammatory accidents; the sittings lasting twenty minutes from the insertion of the positive and negative electrodes the depth of eight centimetres; a current of from forty to fifty milliampéres; and, after the extraction of the needles, the closing of the cutaneous orifice with collodion.

Dr. Margary, of Turin, advocated supravaginal amputation of the uterus from the vagina as a treatment for fibromata in the posterior uterine wall.

OÖPHORECTOMY AS A REMEDY AGAINST UTERINE TUMORS.

Dr. Wiedow, of Freiburg, said that he had collected the cases in which removal of the ovaries had been performed for uterine tumors, partly from published records, partly from private information. Through the friendly co-operation of a large number of German, Austrian, and Swiss practitioners, he was able to arrive at conclusions as to the lasting influence of the operations, and the subsequent condition of the patients on whom it was performed. The principal point was to show the influence of the operation on the cessation of hemorrhage, and on the diminution of the size of the tumors. He also endeavored to point out whether, and in what way, the result of the operation was modified by the situation and size of the tumor.

Prof. Hegar, of Freiburg, and Sir Spencer Wells took part in the discussion which followed.

THE CÆSAREAN SECTION AND ITS MODIFICATIONS.

Prof. P. Muller, of Berne, read a paper on this subject. He said that the prognosis in Cæsarean sections had been hitherto very unfavorable, the death-rate exceeding eighty per cent. The recent advances in surgery, especially the improvements in laparotomy, had had an influence on the operation, which was shown by the endeavors to successfully combat the loss of blood and sepsis. This object was sought to be attained by two essentially different ways; the modifications were either radical or conservative. In the radical modifications the source of hemorrhage and of septic infection was cut off by the uterus, in the conservative the uterus was retained and an endeavor was made to ward off these dangers by careful treatment of the uterine wound. Both methods had doubtless certain advantages, but theoretical considerations could not support the radical modification. Yet, in regard to this matter, the result must turn the scale; the operation which was attended

with the lowest mortality must be accepted as the best. The death-rate of the radical operation was about fifty per cent.; but trustworthy statistics were wanting with regard to the conservative method, of which there had been as yet less experience than of the former. It therefore remained yet to be decided which operation should be preferred. If the conservative method should gain recognition, another condition would have to be fulfilled, namely, to protect the woman against rupture of the uterus in a subsequent pregnancy, and against the danger of another Cæsarean section; and this would have to be done in a much more satisfactory and safe way than had hitherto been the case in the Cæsarean operation.

INTERMITTENT CONTRACTIONS OF THE UTERUS IN THE DIAGNOSIS OF PREGNANCY AND ITS COMPLICATIONS.

Dr. Braxton Hicks, of London, presented a paper on this subject, illustrated by three cases. He again called attention to the value of this means of diagnosis, and briefly referred to the discussion on his paper in the last Congress, where it was stated that soft tumors of the uterus also contracted at intervals. Presuming this was ultimately found to be correct in general, the cases in which this would interfere with the diagnosis were pointed out, namely, those in which the fœtus could not be felt, and where hemorrhage was urgent, for instance, where the uterus remained constantly firm, as in some cases of blighted ovum, apoplectic ovum. In these there was almost always a history of pregnancy, and of recent hemorrhage; while if there was amenorrhœa or only normal menses, it would be exceedingly rare if it were a soft tumor. He gave three cases, two of pregnancy complicated with uterine fibromata. In the third one, of extreme obliquity of the uterus, it was difficult to say how much was uterus. In all the cases, the exact relation of the uterus was clearly and readily made out by means of the alteration which occurred at short intervals in the density of the uterus.

ANTISEPTICS IN LAPAROTOMY.

Prof. Mikulicz, of Cracow, began by referring to the necessity of antiseptics in laparotomy as well as in all other operations attended with loss of blood. The principles of the use of antiseptics in laparotomy were the same as in other great operations; but the details differed essentially in some points. This depended on the peculiarities of the peritoneum, which in some respects favored, while in others they impeded the application of antisepsis. The most important properties of the peritoneum having an influence in antisepsis were, first, the great extent of surface, which was a source of danger of cooling on exposure, of rapidly spreading inflammatory and septic processes, etc.; seeing its great power of absorption and excitation, the first leading, in septic peritonitis, to general septic infection, while, in the healthy peritoneum, it prevented the accumulation of large masses of secretion; thirdly, the liability to pour out plastic exudations, and to rapidly form firm adhesions; in this way, foci of inflammation might be localized, and ligatures and separated masses of tissue encapsuled. With regard to antisepsis in laparotomy, attention was directed to the following points: 1. The peritoneum is more easily affected by septic infective matters than any other tissue. Besides this, it was not possible to use, as with wounds of other parts, very active antiseptic measures, such as irrigation with carbolic acid and other powerful means, as, on account of the rapid absorption, the danger of poisoning by the antiseptic was very great. Again, while drainage was of great use in wounds of other parts, it was useless in the peritoneal cavity, and could not obviate the results of infection of any kind. For these reasons, the chief point to be attended to in antisepsis during laparotomy was the absolute withholding of septic materials from the peritoneum; and herein lay the great difference between antisepsis in laparotomy and other operations. In laparotomy, antisepsis was pre-eminently prophylactic. The cleansing and disinfecting of everything which was to be used in or had any relation to the operation must be carried out much more thoroughly than in other operations. The spray was superfluous in faultlessly clean rooms; but in hospitals it should be used for half an hour to an hour before the operation, for the mechanical purification of the air. During the operation it was useless. In operations on the stomach and intestines, the absolute prevention of the escape of the gastric or intestinal contents was one of the most important points in antisepsis. Drainage of the peritoneum was nearly always quite superfluous in operations performed aseptically; it might even be dangerous to allow infection of the periosteum to take place through the drainage openings. Complete drainage of the peritoneum by the methods now in use was, on mechanical grounds, altogether impossible. Hence drainage was permissible in laparatomy only in rare and exceptional cases. 2. Besides direct infection during the operation, spontaneous infection might occur in the peritoneum in certain conditions. It occurred when a large quantity of fresh, especially serosanguineous fluid collected in the peritoneum and was not rapidly absorbed. In this was developed bacteria, which led to decomposition of the secretion, and infection of the peritoneum. Hence the second great principle of antisepsis in laparotomy was to prevent the collection of secretion in the peritoneal cavity. Any means which limited the amount of secretion in the peritoneum or favored its absorption was a part of antisepsis in laparotomy. An accurate "toilet of peritoneum" was of the first importance; next came the prevention of secreting wound-surfaces in the peritoneum by various means, such as ligature *en masse*, cauterization of the pedicle and of adhesions, suture of the wounded surfaces, *e.g.*, of the ligamenta lata or of the stump of the uterus (as in Schröder's myomotomy), the shelling out of tumors having a wide base or lying behind the periosteum, followed by suture of the peritoneal covering to the abdominal wound, so as to shut off the entire surface of the wound from the peritoneum. Everything also must be avoided which might too powerfully excite the peritoneum to secretion; *e.g.*, irritation by strong antiseptics. To favor absorption, a compressive bandage should be applied over the whole abdomen; it also fulfils the necessary object of keeping the abdomen at rest. With regard to the material used for ligature, catgut and carefully disinfected silk were equally good from an antiseptic point of view. The pedicle might be treated either extraperitoneally or intraperitoneally, so long as the abdominal cavity was perfectly closed. The manner in which the sutures were applied to the abdomen has no influence, provided that the surfaces of peritoneum were properly united. Any special method of dressing the wound was of very little importance, provided that no drainage-tubes were introduced into the abdominal cavity. A narrow strip of material, rendered antiseptic, was quite sufficient for the dressing of the wound; and for this purpose, solution of carbolic acid was the best and safest means. Large quantities of iodoform were dangerous, on account of the liability to poisoning; but Dr. Mikulicz had with advantage applied it in very small quantities to the pedicle and to the sutured stump of the uterus.

INTERNATIONAL NOMENCLATURE IN OBSTETRICS.

Prof. Simpson, of Edinburgh, submitted a report on this subject, which he had brought before the Congress in London in 1881. At that Congress, a committee had been appointed to consider the matter and report to this Congress; but, practically, nothing had been done by the committee. The section now reconsidered the matter, reaffirmed its importance, and requested the committee to go into it afresh and report to the next Congress.

THE SIGNIFICANCE OF ALBUMINURIA IN PREGNANT WOMEN.

Prof. Halberstma, of Utrecht, in a paper on this subject, said, in the first place, that the facts observed did not permit his recognizing, as the cause of albuminuria in pregnant women, a reflex contraction of the renal arteries; second, albuminuria in pregnant women was specially observed when there was a want of proportion between the size of the gravid uterus and the abdominal cavity; and, third, the cause of albuminuria in pregnant women was, in the greater number of the cases, the tension and compression of the uterus.

SOME DIAGNOSTIC DIFFICULTIES CAUSED BY HYPERTROPHY OF THE CERVIX UTERI.

Prof. Howitz, of Copenhagen, pointed out that, in cases of hypertrophy of the neck complicated by dilatation of the body and fundus of the uterus, special symptoms arose in consequence of change of the anatomical relations. In cases of pregnancy, especially in the first months, this condition gave rise to diagnostic difficulties. The elevated situation of the uterine enlargement, its strange mobility, its elasticity and situation, were characteristic guides in such cases. The fœtal *bruit* could also be heard sooner than ordinary. A careful examination by the vagina and rectum would give precise information as to the exact condition of the uterus.

Dr. Priestley, of London, said he had seen cases very analogous to those described by Professor Howitz, which produced, not difficulty in diagnosis, but difficulty in accouchement. It was a question well deserving of consideration, whether, in certain cases, some operative measure might not be adopted.

THE OPERATIVE TREATMENT OF EXTRA-UTERINE PREGNANCY.

Prof. Werth, of Kiel, said that operation was indicated in the early months of pregnancy when the fœtus, being dead and lying in Douglas' pouch, produced severe symptoms of incarceration. On the other hand, laparotomy was without object when it was concluded that rupture of the sac had taken place, and experience up to the present time was in favor of expectant treatment. When pregnancy was more advanced, and the embryo was alive, operation gave little prospect of saving the child, and was of unfavorable prognosis for the mother, except in cases where the anatomical conditions favored the removal of the entire ovum with its membranes. Hence it was a principle to avoid operation while the child was alive, and to wait for its death. The expulsive movements following the death of the embryo could, as a rule, be held in check by appropriate means. As the extra-uterine position of a fœtus which had died after having passed beyond the first stages of development was a source of danger to the mother's life, removal by operation of the dead fœtus was necessary. The prognosis was incomparably better than that of operation during the life of the fœtus, provided that a suitable time was chosen for the operation. This, whenever possible, should not be performed before arrest of the circulation in the maternal placenta might be supposed to have taken place; namely, from the tenth to the twelfth week after the death of the fœtus. Speaking of the methods of operation, Dr. Werth said that, in the rare cases of prolonged pregnancy in the outer part of the Fallopian tube or in the ovary, with simultaneous unfolding of the broad ligament, extirpation of the entire sac was indicated; the operation was like ovariotomy, and the prognosis was similar. As a general rule, the sac should be sutured to the abdominal wound. The placenta and membranes of the ovum should be removed, if there was no doubt as to the previous occlusion of the placental sinuses by thrombosis. If strict antiseptic precautions were followed during the operation, and an occlusive dressing applied, then neither preventive drainage through the vagina nor permanent irrigation of the sac was necessary, provided that decomposition of the contents of the sac had not already set in. Both these were to be avoided, as well as washing out and plugging the sac when the operation was performed during the life of the embryo or shortly after its death, and when artificial or spontaneous detachment of the placenta threatened fatal hemorrhage. On the other hand, the author recommended in these circumstances the partial filling of the fœtal sac with some substance (tannin and salicylic acid in equal proportions, according to Freund), which might enable the placenta to remain aseptic until it was thrown off at a later date. Elytrotomy was preferable to gastrostomy only in some rare and peculiar cases. With regard to the proceeding recommended by Martin, of partial removal of the fœtal sac, suture of the remaining part, and drainage through the vagina, further experience was required before a decision could be arrived at as to its general applicability.

THE EARLY PERFORMANCE OF OVARIOTOMY.

Mr. Knowsley Thornton, of London, read a paper on this subject. He first considered whether it was ever right to interfere with an ovarian tumor by tapping or by aspiration. Spencer Wells, Keith, and Thomas were in favor of tapping; and many other leading ovariotomists encouraged it. He gave quotations from Gross, Emmet, and Lawson Tait against the practice; and referred to the doubtful advantages claimed for this proceeding compared with its dangers and its immediate and remote mortality. He said that exploratory incision was far safer and better in doubtful cases. Tapping should be condemned, except in some very rare occasions. He would always remove an ovarian tumor as soon as it was large enough to be abdominal and slightly stretch the parietes. There were objections to operating earlier, except in special cases. The danger was in delay. Pathological changes in the cysts might lead to the escape of their contents, and to the formation of adhesions; or the pedicle might become twisted. He adduced illustrations of the dangers of delay, drawn from over four hundred ovariotomies he had performed, including forty cases in which ovarian fluid was free in the peritoneum, and thirty-four cases of twisted pedicle. He then summed up by considering the following questions: 1. Is tapping ovarian or parovarian cysts, or cysts of the broad ligament, ever justifiable; and if so, what conditions justify it? 2. Can any fairly general and defined rule be laid down as to the proper time at which to perform ovariotomy; and if so, what conditions justify an earlier or later operation? He concluded by appealing to the profession to still further improve the brilliant results of ovariotomy by condemning tapping and supporting early operation.

MANAGEMENT OF THE THIRD STAGE OF LABOR.

Prof. Stadfeldt, of Copenhagen, read a paper in which he gave the result of the expectant method of treatment, Credé's method, and the Dublin method. In the expectant method, as practised in Copenhagen, the placenta was allowed to become detached spontaneously, and to escape into the vagina, unless severe hemorrhage indicated earlier removal of the contents of the uterus. As a rule, the detachment of the placenta took place within about two hours. In Credé's method, circular frictions of the fundus uteri were made immediately after the birth of the child, and during a strong after-pain, generally the third, the placenta was pressed out by a combined concentric and pushing down pressure on the fundus and body of the uterus. The Dublin method was described in somewhat different terms by different authors. As a rule, the chief importance was attached to pressure on the fundus uteri immediately after the birth of the child. This, he thought, tended to increase anteflexion, and thereby to impede the escape of the placenta. He had, therefore, applied friction to the fundus uteri, as in the first stage of Credé's method, and when the placenta

had escaped into the vagina, it was easily removed by the help of two fingers, with simultaneous gentle traction on the umbilical cord. In a few cases, where the placenta was not expelled at the end of half an hour, he made a depressing movement through the fundus. When these methods failed, the placenta was removed by the introduction of the hand into the uterus. Dr. Stadfeldt had treated a large number of cases by each of the three methods above named, and gave results. From his statistics he excluded all cases of abortion and of placenta prævia, cases in which the contents of the uterus were putrid, and some cases of very difficult labor. From April 1, 1873, to March 31, 1877, he followed the expectant method in 1,780 cases; from September 1, 1877, to February 1, 1881, Credé's method in 1,611 cases; from May 12, 1882, to February 15, 1884, the Dublin method in 971 cases; and from February 16 to May 30, 1881, the expectant method in 198 cases. The results indicated that, when compared with the expectant method, that of Credé was preferable. Detachment and reunion of the membranes, or of small portions of placenta, indeed, occurred more frequently, but the preponderance was not great (2.3 against 1.8 per cent.), and any danger might be obviated by the use of antiseptics. On the whole, it seemed to him that the objectors to Credé's method were wrong in attaching too much importance to its disadvantages, and overlooking the fact that it removed the dangers attendant on the expectant method during the time of waiting, especially outside lying-in hospitals. It could not, however, be denied that the proper and safe application of Credé's method required so much intelligence and accuracy that it might be attended with danger in the hands of unskilful persons, and, therefore, it was not thought right in Copenhagen to teach it to midwives. On the other hand, the Dublin method was easily learnt, and was free from the dangers of the expectant and Credé's methods; on the one hand, it diminished the danger of flooding and of retention of the placenta; and, on the other, removed the danger of separation and retention of the membranes. It had been said that Credé's method, by favoring retention of the membranes of the decidua, was more liable than the expectant method to give rise to puerperal disease and mortality. The contrary was the result in Dr. Stadfeldt's experience; the figures given being, with the expectant method, for disease, 24 per cent., and for mortality, 1.9 per cent.; with Credé's method, disease, 18.3 per cent., mortality, 0.6 per cent. In both series antiseptics had been used with equal energy. He believed that, in the present day, retention of the membranes had little influence on puerperal disease and mortality, provided that strict antiseptic precautions were carried out during labor, and that the accoucheur abstained from unnecessary meddling during the lying-in period. Large portions of decidua might even be left in the uterus without becoming septic, and without giving rise to self-infection of the patient.

CONGENITAL LATEROPOSITIONS OF THE UTERUS, ETC.

Prof. Lazarewitsch, of Kharkoff, addressed the Section on the congenital lateropositions of the uterus in their relations to the mechanism of labor and to the peri-uterine tumors. These congenital lateropositions were, he said, frequent, especially those in which the uterus was completely displaced to the left. Those which depended on the development of pathological growths must be chanced to other positions, and on that account must be called accidental. But if they depended on a defect in the development of the broad ligament, or of the lateral wall of the vagina, these positions were invariable, and did not alter during the growth of the tumors, whatever these might be, which were formed round the uterus, any more than during the period of pregnancy. If the lateral position of the uterus was sufficiently marked, the anterior position of the recto-uterine pouch, being displaced by the uterus, took an oblique shape; and the ovary, which corresponded to the large side of the peri-uterine space, being pressed upon, often lay above the peri-uterine pouch, and fell down more or less. The ovary of the opposite side, not finding place near the uterus, was ordinarily raised up and passed above the upper entrance to the cavity. According as the one or the other ovary became cystic, the cyst either remained for a longer or shorter time in the deep cavity, and in its growth displaced the uterus forward and upward, or, from the beginning of the growth, was found above the deep pelvis and the uterus, leaving it free. If the ovary corresponding to the large side of the peri-uterine space became cystic, the pedicle of the cyst was ordinarily long; and on the contrary, it was short if the cyst belonged to the ovary on the smaller side of the peri-uterine space. Thus, so far as the lateral position of the uterus was concerned, one was not able to say to which of the ovaries the cyst belonged; but, if one knew to which ovary the cyst belonged, one could estimate the length of the pedicle. Being turned to one side, the uterus left free entrance to the recto-uterine pouch; and, for this reason, the blood of the pouch could spread in all directions. If the uterus was turned to one side, it was difficult to say that it was completely inclined, or bent forward or backward; it was in this event that the cases of lateroversion and lateroflexion were met with. In the case where the uterus was turned to one side, pessaries could not maintain it, owing to the difference in the length of the lateral walls, and the different heights or lateral arches of the vagina. One was often deceived as to the origin of the pain felt sometimes on one side in the lower part of the abdomen, particularly during menstruation, in attributing this to the ovary. This pain most often proceeds from the laterally displaced womb. The congenital lateropositions, as well as the lateroversions of the womb, had an evident influence on the mechanism of labor, but this influence was not proportional. In the lateroversion the womb, increasing during pregnancy, preserved its regular form, changing only the direction of its axis; whereas, when displaced in the lateroposition, it preserved the direction of its axis but changed its shape, because, on the side on which it approaches one of the lateral walls of the pelvis, its lower segment did not expand, or expanded very little, while the segment on the opposite side underwent the sacciform expansion. During labor one could easily do away with the lateroversion of the womb by making the woman assume a suitable position, or by keeping up, by means of the hands, the corresponding side of the womb. But these measures became useless if the womb was in the state of lateroposition. In this case, it was enough to introduce the finger into the neck of the uterus, and to draw it toward the middle of the pelvis.

STATISTICS OF PUERPERAL FEVER IN DENMARK.

Dr. E. Ingerslev, of Copenhagen, read a paper in which he gave a brief summary of a research into puerperal mortality in the towns of the Danish provinces and in Copenhagen for the last seventeen years. The principal aim of the paper was to explain how the difference between the mortality in the maternities and outside of them, elsewhere brought into such strong relief, had lost its *raison d'être*, since it was proved that the antiseptic measures to be taken in labor were still less performed outside of maternities. He also stated his opinion that matters were, up to this time, nearly as successfully managed in the towns as in the country districts of Denmark. Dr. Ingerslev went on to show the ravages of puerperal fever were most manifest when one looked at the proportion between the puerperal mortality and the total mortality in women from fifteen to forty-five years of age, that was to say, of the age at which labor generally took place. In this regard, a great resemblance was found between this and like researches made a short time back in Prussia. The great difficulties in the way of finding a fairly exact expression for the puerperal mortality would be, perhaps, best overcome in a small country, where one could most easily obtain a general

view of things, and make requisite corrections by addressing oneself to medical men for the necessary explanations. He had made the attempt for a period of some years, and in this way had made a calculation of the mortality as near as possible, and showing, at the same time, a minimum of errors. The calculation, so checked, showed an evident decrease in the puerperal mortality, which undoubtedly was due to a more strictly antiseptic conduct of labors even outside the maternities.

THE UTERINE ADENOLYMPHANGITIS.

Dr. Martineau, of Paris, read a paper on the above condition "as a cause of the so-called peri-uterine troubles and its importance for the treatment of the inflammation of the uterus." He took the view that the uterine and peri-uterine adenolymphangitis was closely connected with uterine inflammation. Acute or chronic metritis could not exist without the uterine and peri-uterine lymphatic system sharing in the inflammation of the uterine tissue. Peri-uterine adenolymphangitis was the origin of the inflammatory accidents called peri-uterine, such as phlegmon of the broad ligament, peri-uterine phlegmon, perimetritis, and pelvic peritonitis. The designation of these conditions by the names adenophlegmon of the broad ligament, peri-uterine adenophlegmon, adenopelvic peritonitis, was that which suited them, because it recalled their origin and pathology. The peri-uterine adenolymphangitis being equivalent to uterine inflammation, every cause which would have as a result the increasing of this inflammation would at the same time increase the peri-uterine adenolymphangitis, and bring about the accidents of which it was the origin. Adenolymphangitis, when there was a question of instituting local treatment, the treatment of the lesions of the metritis, gave the indication and contra-indication for the treatment, as pathogenic and nosological treatment could produce an excitation of the uterine inflammation.

A NEW ELECTRIC TREATMENT OF PERIMETRITIS.

Dr. Apostoli proposed "a new electric treatment of perimetritis by double faradization of the uterus." He described, in the first place, the modification which he had introduced in the manual application of uterine faradization (A. Trifner's method); and he enumerated its general advantages in the treatment of simple metritis. He applied his method also advantageously in perimetritis, and described the manual method, the dose, duration, and intensity of the application. Summing up, he had always found the faradic currents, of high tension, feeble dose, and long duration, relieve every perimetritis, even acute, and bring about its rapid resolution.

TREATMENT OF PUERPERAL FEVER BY COLD BATHS.

Prof. Vincent, of Lyons, said: 1. That the administration of cold baths was practicable with the recently delivered attacked with puerperal fever. 2. That cold baths were free from danger in the puerperal state. 3. They had a certain and quick antifebrile effect in the sequelæ of delivery. 4. Recovery from puerperal fever was the rule with treatment by baths of proper temperature and methodically administered. 5. Cold baths were indicated in all high temperature forms of after-complications of childbirth, the very acute peritonitis excepted. The indication for cold baths did not arise except where the fever was kept up, without notable morning remission, to about 40° Cent., when the powerlessness of quinine and diffusible stimulants in full doses had been shown, and when, in fine, the lochias were fetid, and intra-uterine injections had been carefully tried without bringing a fall in the febrile condition. 6. Cold baths should be administered at a temperature varying from 28° to 18° Cent.; according to the fall secured by the first bath, given at 28° or 30°, the temperature of the subsequent baths should be reduced. (The rule was, to get with a cold or tepid bath a fall of from one to two degrees of the patient's temperature.) The method used in typhoid fever, treated by cold baths after the system of Dr. Brand, should be followed, with modifications. 7. The cold baths were repeated every three hours until the temperature had fallen to 38°, and stayed there, with only ascending oscillations of some tenths in the evening. 8. When baths of 18° or 20° repeated every three hours, night and day, did not bring about a notable reduction of temperature, a large ice-bag should be placed in the intervals of the baths, on the abdomen of the patient. 9. Along with the cold baths and the ice-bags, spirits and tonics should be freely administered; the patients should be fed with liquid or semi-liquid foods, having much nutriment in a small bulk—soups, beef-tea, American broth, milk, etc.

Dr. Marcy, of Boston, advocated the restoration of the perineum by a new method; and Dr. Zambaco, of Constantinople, submitted to the Section some "Physiological and Pathological Remarks upon the Women of the East."

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

ALCOHOL AND THE HEALTH EXHIBITION—DR. MOXON ON LORD TENNYSON—ONSLAUGHTS ON DOCTORS—SMALL-POX AND VACCINATION—DECREASE OF THE EPIDEMIC.

London, August 30, 1884.

The Health Exhibition continues to attract shoals of visitors. I must confess that my own experience of it has been very disappointing. A good many of the exhibits are very interesting and some of them instructive, but what possible relation many of them can be said to bear to the subject of health I cannot say. Lace-making, glove-making, candle-making, and so on, are all interesting in a way, but what place have they in a health exhibition? The same remark applies to the Chinese and Japanese Courts—entertaining as the latter are. The number of alcoholic exhibits and the space occupied by some of them would certainly lead a superficial observer to imagine that, in England, alcohol is a *sine qua non* of health. The "intelligent foreigner" who visits the Exhibition, would perhaps be surprised to learn that there are now nearly a million of total abstainers in Great Britain, including some hundreds of medical men. Although not an abstainer myself, I cannot but think that the wholesale admission of alcoholic exhibits is calculated to do harm. Their presence in such an exhibition gives them a position, so to say, and people will be tempted to imbibe alcoholic drinks more freely than heretofore, because "they have been shown at the 'Health.'" The gratuitous distribution of glasses of wine and beer (*as samples*) by the exhibitors, does not look at all well. The Council have at last forbidden it as regards the beer, but it still goes on as regards the wine.

The poet-laureate has received the hardest blow I should think he ever had administered to him. In the current number of *The Lancet*, in a most striking and suggestive paper on the late Dr. Hilton Fagge, Dr. Moxon takes Tennyson to task for his foul libel on the medical profession in his volume of ballads published at Christmas, 1880. I cannot resist quoting a piece:

"Fagge's greatness as a physician appeared in his always kind and sympathetic and Christian treatment of the sick poor. It is easy for poets to put their own denials of Christ into other people's mouths, and then as fashionable authors to spread them about on drawing-room tables. It is convenient to be able to work off your baser sentiments in a false character; you yourself then appear pure by contrast with your own creations. But if one's solemn everyday duty is spent face to face and eye to eye with the sorrowing and suffering poor, one wonders how even a poet-laureate could be capable of think-

ing the matter of those loathsome lines of this new peer. I wonder is he yet ashamed of them? What footing has this poet aristocrat on any grounds of charity that justifies him in putting his blasphemous sentences into the mouth of the child he supposes? Let him go into a children's hospital, and see how far the poor sick little ones think as vilely as he of the kind-hearted doctor, whose only sorrow is that his best help to his little patients too often proves ineffectual. Fagge was physician to the Evelina Hospital for Sick Children. His sympathies were not with grandeur and the House of Lords."

This is harsh but not undeserved, as those who have read through the poem referred to will admit. Many of our profession are doubtless reading Dr. Moxon's denunciation of the laureate with keen appreciation. The whole of the paper is well worth reading—a remark that applies to all Dr. Moxon's writings.

The poet-laureate is not alone in attacking the profession. On taking up a religious newspaper yesterday, I found a long letter inserted in which a furious onslaught was made on doctors generally, and their treatment of hospital patients in particular. The same journal stated some time back, in an editorial on sanitation, that the doctors were anxious to bring every one under their "tyranny." Such thanks do we get for trying to check the spread of disease—a step which directly tends to impoverish us.

I saw a little time since in a radical weekly journal, in the course of a controversy then raging in its pages on the subject of vaccination, a letter in which the writer said that doctors supported vaccination because it was profitable! I was greatly tempted to write and give the obvious answer, that we certainly did not advocate vaccination on that ground, as even if it did pay, it did not pay a fractional part of what small-pox used to. Thirty years ago it formed a very important part of a doctor's practice. Now many never see a case. The recent epidemic, which began to excite some alarm, has almost subsided.

The anti-vaccinationists are very active. At Leicester—one of their strongholds—twelve hundred persons are shortly to be tried for non-compliance with the Vaccination Acts.

OUR PARIS LETTER.

(From our Own Correspondent.)

DR. BURQ AND METALLOTHERAPY—PROFESSOR BOUCHARDAT DOES NOT BELIEVE UNHEALTHY LODGINGS SO IMPORTANT A FACTOR IN THE PATHOGENY OF DISEASE AS IS GENERALLY REPRESENTED—A BLOW TO SANITARIANS—THRIVING IN SPITE OF DIRT AND BAD AIR—HOW PROFESSOR BOUCHARDAT LIVES—PARIS DRINKING-WATER UNJUSTLY ABUSED—THE CHOLERA IN FRANCE.

PARIS, August 29, 1884.

DR. BURQ, the founder of modern metallotherapy, which is also called Burqism, as you are aware, died on the 17th inst. at Bièvres, where he had gone for a holiday. He was sixty-two years of age. It is not necessary for me to enter into the peculiar notions he held respecting the action of metals in the economy, particularly those connected with the efficacy of copper as a preventive and curative agent for cholera, as they are well known. The theories which Dr. Burq had promulgated, for the first time as far back as 1852, were brought to the notice of the Paris Academy of Medicine, and although his communication was supported by Trousseau and Bouchut, it was received with little or no favor. He then retired almost into obscurity, and no more was heard of him till 1877, when he published a series of papers to the effect that the application of certain metals on the skin determined, in anæsthetic patients, and sometimes in those organically affected, certain important modifications, the principal being the return of general and special sensibility. Moreover, he added, all patients were not sensible to the same metal, and that gold, iron, and copper produced positive or negative results according to the subjects. The experiments of Dr. Burq were verified by Professor Charcot, at the Salpetrière Asylum, where this system is frequently resorted to; but I cannot say that it has been generally adopted in France or elsewhere. Like most inventors, Dr. Burq did not derive much personal advantage from his discovery, and he died almost penniless.

Professor Bouchardat does not consider unhealthy lodgings so important a factor in the pathogeny of disease as is generally represented in the profession. He believes that this idea has been greatly exaggerated, and while admitting that, all things being equal, people badly lodged contribute greatly to the general mortality, but it is only when they are at the same time subjected to the pangs of misery—which are much more terrible—insufficient and irregular alimentation, excessive work, and then alcoholic and other excesses. In a recent lecture at the School of Medicine, Professor Bouchardat developed the subject in the following terms: "It is certain that, during the night, the respiratory organs, like the other organs of the body, perform their functions less actively, and that if, outside the hours of sleep, one works moderately in the open air, the health will not sensibly suffer from the insalubrity of lodgings. The peasants are not better lodged than citizens, their food is not so good, and yet their health is more robust. Even among citizens, those who work hard, but in the open air, are less susceptible to disease than the others." M. Bouchardat cites the example of the chiffonniers who live crowded together in huts, as less affected by disease than the average of the working classes. The necessity for pulling down unhealthy lodgings to replace them by palaces is not so much felt as is represented, and even when all the lodgings are improved, the public health will not be much influenced by it, so long as the other causes of disease are in existence. The learned professor adds that it is imagined that the privies and night-soil are powerful causes of the propagation of contagious diseases in large cities, an assertion offered gratuitously and without any scientific proof, and he brings forward the sewer-men (égoutiers), the night-men, and others who work in the general deposits of night-soil (dépotoirs), the inhabitants of Gennevilliers (just outside Paris), who water their cultures with the waters from the drains of this city, which are rich in night-soil, as not offering a greater contingent of victims to contagious diseases than those who live more comfortably. In fact, Professor Bouchardat may present himself as an example of his thesis in point, as he lives in one of the filthiest quarters of Paris, in a house he has occupied for nearly half a century, and yet he has long passed his threescore and ten without having a day's illness, and he does not recollect that the inhabitants of the little street he is living in, which is a dark dirty lane in the old city, near the Nôtre Dame Cathedral, have been more stricken with disease than those of the modern palaces in the Boulevards.

With reference to the mortality of Paris being greater than that of the other cities of France, Professor Bouchardat attributes this to another cause: misery and the conglomeration of unacclimatized individuals, who for various reasons are attracted to this city, and who in the case of an outbreak of any epidemic disease, are the first to be affected. The hospitals become crowded with them, and it is by them that the mortuary list is swelled. It is thus he explains the great mortality from typhoid fever in Paris, yet it is not the less true that the causes are local.

In the debate that is being drawn out at the Academy of Medicine anent the cholera, M. Bouchardat observed that the drinking-water in Paris has been greatly and unjustly abused, particularly by foreigners. He declared that the potable water distributed in Paris, even that furnished from the Seine and canals, is excellent, and may be drunk with impunity, provided it is properly filtered.

M. Bouchardat, who seems rather inclined to be personal, again puts himself forward as an example of the innocuous influence of the Paris water, which he has been drinking for so many years, and he holds up also M. Chevreul as another example, this eminent chemist being on the eve of entering his ninety-ninth year.

The cholera is still lurking about the south of France, but the epidemic is localized in the departments in the littoral of the Mediterranean. There has been rather an increase lately in the mortality at Toulon and Marseilles, which has been attributed to the return of the fugitives and to the continued insanitary condition of these places.

PERIOD OF GREATEST RISK FROM CONSUMPTION.

To the Editor of The Medical Record.

SIR: The communication of Dr. Marsh in your issue of August 16th has come to my notice on return from vacation.

The facts and figures were not supposed to be new, nor the conclusion previously unknown, but they certainly have never been accepted as established.

Over and over again the subject has been presented in various journals, and your own issue of August 30, 1884, calls attention to the publication of an article by Dr. Baker, of Michigan, issued in 1872.

The material in my possession on the subject renders amusing the possibility of my ignorance of the views of the authors to whom your correspondent alludes; but drawing from this material, and using only such as considerable labor warranted me in believing reliable, I was struck with the aggregate force of the information, and sought to call this, and this only, to the attention of the profession

The work alluded to by Dr. Marsh, and for which the compiler is entitled to great credit, is not a private or unknown document, but an open book, issued by the Mutual Life Insurance Company for its own purposes, and for several years well known to the public, as well as to medical men, and I certainly have no desire to gain credit for what is already public property.

The reliability of figures published by Life Insurance Companies would seem to render superfluous the considerable labor sarcastically alluded to by your correspondent. Nevertheless, all the material drawn upon, and much not used, was carefully gone over, as far as the original facts were attainable, and the experience of the Mutual Benefit subjected to a like investigation; but as I did not suppose it necessary to say that the experience of the Mutual Life was compiled by other hands, so I did not suppose I was claiming credit for any others that I might choose to select as equally reliable.

Had your correspondent taken the very slight trouble to notify me by letter, or otherwise, of failure to give credit to himself or the company he represented, it would have been promptly accorded.

Dr. Baker, with becoming modesty, claims even the diagram, or a similar one, and to this originality he is welcome, if only the views presented, *old to a few, new to the many*, receive attention.

EDGAR HOLDEN, PH.D.

NEWARK, N. J.

HIPPOCAMPUS *VS.* HYPOCAMPA.

To the Editor of The Medical Record.

SIR: Among the changes from the nomenclature now in use, suggested by Wilder, is the adoption of "hypocampa" for "hippocampus." His chief reasons are the occurrence of this term in Vicq d'Azyr's work, and a morphological one to be referred to. It is difficult to see what is to be gained by this adoption of what may be the product of a typographical error in Vicq d'Azyr's work, who, quoting Arantius and Varolius as the discoverers of the hippocampus, gives "hippocampus" as the name in his glossary of anatomical terms, and *hypocampe*, with the Latin forms *hypocampus* and *hypocampi* in several figure references. The transformation of a hastily written "ip" to a "y" is a common one with printers, and may have been indulged in by the old copyists. The use of the term by the discoverer is, we think, the determining factor here. Although Arantius is not accessible to us, yet there is a very full citation of his description in that magnificent work, Burdach's "Vom Bau und Leben des Gehirns." He cites Arantius (page 45, chapter iii., of the latter's observations) as the discoverer of the *hippocampus*, and as he is exceedingly accurate in citation, his work being the most complete and painstaking bibliography of the subject of cerebral anatomy up to the year 1819 extant, it is to be assumed that he saw the original lines when he says "Arantius discovered it, and described it as a white prominence resembling a *hippocampus* or a *vermis bombycinus*,[1] which having its head in the third cavity, extends through the inferior cornu, circumscribes the crus, and ends anteriorly with a bent round tail." That some obscure resemblance of the head to the fish known as the sea-horse, or hippocampus, was before Arantius in penning this description, I think there can be little doubt.

Wilder has possibly been misled by the accepted use of the terms *pes hippocampi major* and *pes hippocampi minor*, which are both manifestly improper. On this head Burdach is again very explicit and satisfactory. He says that of the term hippocamp, by a curious misunderstanding, the authors—instancing Mayer—made *pes hippocampi*. Inasmuch as the sea-horse has no foot, either large or small, Mayer and Reil endeavored to elude the quandary, by using the term *pes hippopotami*. The question is disposed of by the adoption of "calcar" for the eminence in the occipital horn, and "digitationes" for the series of eminences in the temporal horn of the ventricles, so that hippocampus may be retained for the gross prominence of the involuted cerebral wall, as "cornu ammonis" indicates its appearance in section.

Burdach has a dozen references in his foot-notes to Vicq d'Azyr's figures, which indicate a detailed and attentive study both of these and of the text of that work. His silence on the subject of hypocampe—since he was at one and the same time an excellent classical scholar, a painstaking reader, and acquainted, as is evident, with the older literature beyond even Vicq d'Azyr—seems to indicate that he regarded it as a printer's or clerical error, and relied on the list of anatomical terms furnished by Vicq d'Azyr as the proper interpretation of the latter's nomenclatural views.

It is singular that Burdach, who in the two hundred and seventieth annotation of his second volume cites the entire literature regarding the hippocampus, and who was so thoroughly acquainted with Vicq d'Azyr's work, should fail to note Varolius as sharing in the discovery of the hippocamp, which Vicq d'Azyr maintains. Arantius and Varolius were contemporaries, both made their discoveries at Bologna, and published their treatises at nearly the same time. Of the two the great Varolius was undoubtedly the one most deserving of the title Genius, and as much in advance of his day as Willis was of his, but it must not be forgotten that Arantius was a close observer, and devoted special attention to the temporal cornua, which he erroneously elevated to the position of independent cavities, capable, as the primitive anatomy of that time permitted him to say, of taking up air! The omission of Burdach's—if it be such—is the more remarkable, as in his historical chapter, when he arrives at what he calls the "sixth period" of cerebral anatomy (1573–1641), he designates it the period of Varolius, and opens its consideration with these lines: "With deepest veneration I mention Varolius (1573) one of the greatest names which the history of our science reveals." The close of the paragraph seems to indicate that there

[1] Caterpillar of the silk-worm.

were at that time in Bologna, as to-day in New York, men whose work was done on the same plan as that shown in a recent much-criticized "Anatomy of the Nervous System." But nowhere does Burdach, although he gives a summary of Varolius' contributions, assign to him any connection with the earlier descriptions of the hippocamp. Aside from Arantius, he gives the names of the following as having variously described and interpreted this body: Marchetti, Molinetti, Duvernoi, Morand, Aubert, Winslow, Bergen, Bonhomme, Wrede, Haller, Mayer, and Malacarne. The connection of the hippocamp and the fornix was known to Arantius, who undoubtedly had a clear idea of the gross relations of these two bodies. As Burdach states, all knowledge of the hippocamp was lost after the days of Arantius, Marchetti, and Molinetti, neither Willis nor Vieussens appearing to have known of it or paid any attention to it. The discovery of Arantius was not resuscitated till the days of Morand, being buried in oblivion for nigh a century.

Let the observer look at Plate XX. of Vicq d'Azyr,[1] which represents the temporal cornua of the lateral ventricles as opened from below, and he will appreciate how the older anatomists interpreted the hippocampus. One is almost inclined to suspect that the artist—the general correctness of whose representations is remarkable—has been biassed by the name, for the denticulations of the *fasciola* (*fascia*) *dentata* and the sweep of the body of the hippocamp are made to resemble the characteristic position and the jointed scales of the sea-horse,[2] while the digitations are represented as much as possible like the head of a traditional dolphin, with a distinct eye and snout, inverting Arantius' "tail."

Had it been Vicq d'Azyr's intention to introduce "hypocampe" into nomenclature it would be certainly remarkable that, having used it in the references to Plates VII. and VIII. in a few places, he should resume *hippocampe* and *hippocampus* in the last or fonrth part of the volume. He also uses *hypocampi* as a genitive form. This strikes me as signal evidence that the "y" is a printer's error, as the correct form (as Wilder has it) would be *hypocampae*. Vicq d'Azyr's last reference to these bodies reads "hippocampe," and on one page, that relating to Plate XX., this form occurs just ten times, besides once on the following page, in the heading, as well as in the full-page title. There seems to be—taking the inconsistency of "hypocampi" grammatically, the numerical preponderance of *hippocampe* and *hippocampus* over *hypocampe*, and the way hippocampus is spelled in the glossary—no doubt that Vicq d'Azyr recognized only hippocampe as correct, and that the other form, as I have stated, is a misprint.

Of course, the attributing to the hippocamp of a "foot" was, as Burdach and Reil recognized, improper. The "pes hippocampi," resembles nothing so much as the foot of a cat with retracted claws, and I have a faint recollection of reading the synonym *pes leonis* applied to it, though I may be wrong. Seeing this resemblance, and finding that the "pes" was a part of the hippocamp, the ox and the ass were yoked together—not the first time in the history of medical and zoölogical nomenclature—and a fish became endowed with a cat's paw.

The discoverer of the hippocampus can have had only an animal resemblance in mind, or he would not have used as a second simile a caterpillar. The "ribbing" of the fasciola, suggested to his mind the jointed structure of the fish known as the sea-horse as well as that of insectean *larvæ*.

Wilder asks the question,[3] whether the denticulations of the fasciola are found in other animals than man, and whether they are recent appearances in all cases, and have been accounted for. The finest denticulations I have seen were in the hippopotamus and the common horse; they seem to be better marked in children than in adults. Meynert offers a reason for their existence, based on the alternate distribution of fibres. That they are a very widely spread character of the fasciola is shown by the following list of animals in which their presence has been distinctly noted by me: Man, orang-outang, chimpanzee, *semnopithecus*, *cercopithecus*, *macacus*, *cynocephalus*, *ateles*, hippopotamus, horse, goat, calf, sheep, and in others of which the notes are difficult of access at this moment.

Respectfully, E. C. Spitzka, M.D.

[1] Traité d'Anatomie et de Physiologie, tome premier, Paris, 1786. It may interest the student of history and particularly him who delights in detecting the sarcasm of events, to learn that this magnificent work is dedicated "to Louis XVI., to whom thirteen States of the New World owe their liberty, the sea its independence, Europe peace, France monuments of justice," etc., all of which culminated a little later on the guillotine.

A SUCCESSFUL CASE OF ARREST OF TUBAL PREGNANCY BY GALVANISM.

BY PAUL F. MUNDÉ, M.D.,

NEW YORK.

INSTANCES of extrauterine pregnancy observed at so early a period as to admit not only of a certain diagnosis, but of their successful treatment, are not so common, but that, as yet, each additional case presents features of interest sufficient to warrant placing it on record. Of late, two cases have been reported by Veith, of Berlin, of successful removal by laparotomy of the whole sac in tubal pregnancy, in the first case the diagnosis being obscure, in the second case clearly made before the operation was decided upon. It is possible that at some future time the details of laparotomy may be so simplified that a fatal termination is a rare exception ; but at the present day, in spite of Tait's wonderful results, the fact remains undisputed that every patient whose abdominal cavity is opened incurs the risk of losing her life. So long as that is the case, the majority of operators will hesitate before performing a dangerous operation, when the same result can be obtained, at least so far as a continuance of the gestation is concerned, by an entirely harmless and simple process. Whether now this process, the passage of an electric current through the gestation-sac, is so entirely harmless, and whether it can be relied upon always to arrest the growth of the ovum and its envelopes, and finally whether the ovum so arrested is a safe thing to have in the abdominal cavity *ad indefinitum*, these are points which only additional observations will decide. As a contribution to the settlement of these questions the following case is reported :

Mrs. P. A——, thirty-eight years of age, mother of one child eight years of age, one miscarriage six years previously, consulted me February 6, 1884, in order to ascertain whether she was pregnant. She stated that she had last menstruated during the last week of November, 1883, that she had had connection immediately after the cessation of the flow, December 1st, and not since, as she soon began to feel nauseated, and being afraid of becoming pregnant had avoided intercourse. Her next menstrual period, due about Christmas, passed without a show, but early in January there was some bloody discharge, although much less than usual. She also began to feel colicky pains in the lower part of the abdomen, which, together with the nausea, persisted until I saw her, and were gradually growing worse. She said that her appetite was good, but that she invariably vomited soon after eating. Morning-sickness was not specially marked. When she came to me she had just had a second scanty show of blood. For several days the abdominal pain had produced some faintness, and her weakness had increased considerably. She was a tall, graceful woman, rather thin and pale, and bore traces of suffering in her face. A vaginal examination showed the uterus pushed somewhat to the left side, but slightly, if any, enlarged, and in the right half of the pelvic cavity an oblong, irregular, deeply fluctuating mass of the size of a goose's egg, which could be slightly moved about, causing the uterus to move with it. Bimanual palpation of this mass caused intense pain, and brought on faintness and the colicky, cramp-like pains of which the patient had complained. Large vessels could be felt pulsating through the right vaginal pouch. Feeling confident that the uterus was empty, for it certainly was not enlarged to the size of a two months' pregnancy, I introduced the sound, and it entered toward the left to a depth of three inches. My already formed diagnosis of tubal pregnancy was confirmed by the appearance of the areolæ, and the oozing of colostrum from the nipples on pressure, certainly unusual except as a sign of pregnancy in a woman who had not been pregnant for six years. The breasts were not enlarged, however, although the lady said that they felt rather fuller than usual.

I explained to the patient and her husband what I thought to be the trouble, and the danger of allowing the pregnancy to proceed, and the hope I had of checking its growth by the electric current. But in order to share the responsibility, and as a guarantee of the correctness of the diagnosis, I proposed a consultation with Dr. Thomas Addis Emmet, which was readily agreed to. He saw the patient at his office the next day in my presence, and without giving him my diagnosis, which I told him I had formed the day before, he at once pronounced it to be a pregnancy in the right tube, and advised the galvanic current.

The patient had already felt considerably prostrated before going to Dr. Emmet, where she was obliged to ride in a carriage, although perfectly able to come to me the day before in the horse-cars, and after his examination she had so much pain that I prescribed a morphine suppository, to be taken as soon as she reached home. Fearing that delay might result in a rupture of the sac, I arranged to go to her residence that afternoon with my battery and pass a current through the mass. Accordingly I went there at 4 P.M., and found the lady so much prostrated, that her husband met me at the door with the words, "I fear, doctor, you cannot do anything today." But the danger of rupture was so vivid before my mind, that I preferred to run the risk of producing that rupture by the electricity, rather than what seemed to me the greater risk of allowing the sac to grow even twenty-four hours longer. Placing a leather-covered button electrode in the rectum, and the other pole by a flat sponge on the abdomen over the mass, I passed the current of my newly filled galvanic battery through the sac, gradually increasing its strength to twenty-four cells, and rapidly breaking the current a dozen times or more. The sitting lasted about ten minutes, and the shocks were quite painful. I did not think this current too strong, for I remembered that in one of the successful cases reported, McBurney's thirty-six cells had been used. I left the patient fairly comfortable, no more prostrated than before the application.

Early the next morning I was called, and when I arrived I learned that the lady, whose nausea and retching had continued all night, had sat up in bed toward morning to vomit, had been seized by a violent pain in the abdomen, and had fallen back in a faint. I found her perfectly conscious, but white as a sheet, with pinched, clammy features, absolutely pulseless at either wrist, skin cool, extremities cold. I naturally thought that the sac had ruptured ; the history and present condition clearly pointed to that conclusion. One thing only led me to doubt a rupture, and that was the strength with which the patient could turn about in bed and answer questions. It was evidently a state of collapse, but it did not seem to

me exactly like prostration from hemorrhage. I could not but hope that it might be merely shock from the repeated examinations and the galvanic current through so sensitive an organ as an over-distended tube. I made a gentle vaginal examination and found the outline of the mass as distinct as the day before. In any case, the only active measure, laparotomy, could not be carried out on a patient in so profound a state of collapse as to be pulseless at the wrists; she must simply have died on the table. Hence, if there was a rupture, all I could do was to stimulate her until she rallied sufficiently to justify laparotomy; and if there was no rupture, then that operation was not indicated. I therefore ordered hypodermics of brandy, each containing five minims of arom. spir. ammonia, one to be given every fifteen minutes in different parts of the body (the patient's stomach would retain absolutely nothing), sent for a nurse, and went home for my laparotomy instruments, in case at any moment they should be required. The physician who was hurriedly called in, and whom I found at the bedside when I arrived, Dr. Black, of the United States Army, on leave of absence and temporarily residing in the neighborhood, kindly stayed with the patient, and was relieved later by my assistant, Dr. E. H. Grandin. On my return several hours later, I found the condition unchanged. The hypodermics were continued during the day, some fifty in all being given.

During the afternoon, while on my way to Mount Sinai Hospital, where I was to operate, I met Dr. Charles K. Briddon in the car, and remembering his recently reported case of laparotomy after rupture of a tubal gestation-sac, related my case to him, and the doubt I was in as to whether rupture had occurred, and whether I should operate or await developments. He strongly advised me to operate at once in spite of the collapse, saying that his patient also was pulseless, but that after the operation her pulse rose. I decided to wait, however, still feeling that, after all, it might be nothing but shock.

The next morning there was a faint trace of pulsation at the wrist; gradually it increased, and we began to hope; the retching diminished and the patient could retain cracked ice. Her abdomen was very sore, and she complained a great deal of colicky pains on the right side. To make a long story short, she gradually rallied, began to retain nourishment, and in a week was able to sit up in bed, and in two weeks lie on a lounge. The sac had become somewhat harder, fluctuation was less distinct, pulsation had disappeared, but the mass was not perceptibly smaller. The breasts had become flabby, but they still secreted colostrum. Although there could not be any reasonable doubt of the death of the fœtus after such a series of galvanic shocks, still, to make sure, I thought it best to pass the faradic current through the sac a number of times, and beginning on the sixteenth day after the galvanic sitting, I made six faradic applications to the sac, one pole in the vagina, the other over the mass on the abdomen, using the full strength of a Kidder tip-battery and frequently breaking the current. One sitting per day was given, lasting about fifteen minutes. This treatment caused no pain or shock whatever. From this time on the patient improved rapidly, regained her flesh and color, and by the end of the fourth week was able to go out. The colostrum gradually disappeared from the breasts, but the sac diminished very slowly, so that when I last saw her at my office on May 19th, three months and a half after the galvanic shock, it was certainly still two-thirds as large as at first, although perfectly solid. All pain in it had ceased before she was allowed to go out. Menstruation reappeared on April 12th, and again on May 7th, lasting seven days. The uterus was measured and found to be two and three-fourths inches deep. The lady left for Europe on May 21st in perfect health, and without a complaint of any kind, and is still abroad.

The special points of interest in this case are: first, the occurrence and recognition of the nature of the collapse after the galvanic sitting; and second, the kind of current which should be used, the galvanic or the faradic.

1. As regards the collapse, I have no doubt that it was due to the violent galvanic shocks passed through a highly sensitive organ, at that time even more closely connected than usual with the sympathetic system, and that the previous examinations had already paved the way for such an occurrence.

The recognition of the cause of the collapse was not easy, and I confess that I expected all during that 7th of February to be called upon at any moment to do laparotomy as a last resort. But I wish again to call attention to the one symptom which led me to defer operating, and which, giving it its correct interpretation, as I chanced to do, saved the patient's life, namely, her singular physical strength, while pulseless at either wrist and evidently collapsed in the highest degree. Had I not considered this persistence of voluntary muscular power incompatible with the loss of so great an amount of blood (intra-abdominal, of course) as would produce so severe a collapse, I should probably have done what was the only other thing to do but wait, that is laparotomy, which I do not think the patient would have survived.

2. My experience with the galvanic current in this case leads me to prefer the faradic, which has been successfully used by Landis, Allen, Garrigues, and others, without any of the shock or pain experienced in my case. I do not attribute the shock entirely to the character or strength of the current, for there was undoubtedly some present before it was used, and I am disposed to believe that rupture was impending or had already begun; but I doubt if the shock would have become so severe if I had used the faradic current. But the faradic will need to be repeated frequently and at short intervals to insure success.

Whether the encysted ovum ever gives rise to subsequent trouble by suppuration or septic infection I do not know. As no such result has been mentioned in the reported cases, I suppose it is fair to assume that its growth once arrested it simply shrivels, mummifies, and is no longer recognizable except as a small hard lump, causing no inconvenience whatever.

Although I have heard incidentally of one or two other unpublished cases of extra-uterine pregnancy checked by electricity, I believe this is the twelfth case on record, the eleven others having been reported by Garrigues in vol. vii. of the American Gynecological Society's Transactions.

20 West Forty-fifth Street.

The newspapers state that two persons, one of whom was a physician, have surrendered themselves to the authorities of Norristown, Pa., and have admitted the stealing of the body of John May, a murderer and suicide, from the cemetery at that place. The purpose for which the body was taken is not mentioned, but it was doubtless for dissection. An act of this sort is certainly criminal, but it is interesting to note the trouble the old law-writers have had in determining exactly what kind of a crime it was. They early came to the conclusion that it was not theft, because a dead body could not be property, and no one could be said to have ownership in a corpse. In one case, however, it was held to be robbery, because the grave *clothes* were taken as well as the corpse. In more recent times, the act has been regarded as one against the public instead of an individual, and heavy penalties have been prescribed against those who wantonly open a grave. At the same time most States and communities have laws by which the bodies of unknown and friendless persons are given to hospitals and medical schools for dissecting purposes. Such laws will not, however, permit the removal of the unknown dead from cemeteries where they have been interred in the usual way. Removal secretly of the bodies of such persons is as much an offence as that of persons who are well known and have died surrounded by their friends.

TYPHUS FEVER, AS IT OCCURRED IN AN EPIDEMIC AT THE PHILADELPHIA HOSPITAL, WITH A CONDENSED REPORT OF NINETEEN CASES.

By LLOYD NORRIS HORWITZ, M.D.,

LATE RESIDENT PHYSICIAN TO THE PHILADELPHIA HOSPITAL, PHILADELPHIA, PA.

Although this report embraces but the record of nineteen cases, yet the writer's conclusions and remarks are founded on the close observation and post-mortem examination of over forty cases which occurred in the wards of his colleagues Drs. Elder and Gotwald.

This epidemic of typhus fever began about March 1, 1883, and lasted with more or less severity until June of the same year, and was then only checked by the strict prophylaxis employed by the physicians at the hospital, assisted by the hearty co-operation of the Board of Health, as the contagious, infectious, and epidemic character of the malady, in the writer's opinion, was clearly proven by the cases which fell under his direct observation.

Case I.—F. W——, white, aged thirty-four, admitted to the hospital March 2, 1883, was the second case of typhus fever of the epidemic. Precisely like four-fifths of all the cases admitted, he came from a locality in this city noted for its filth, its unhealthy and unhygienic surroundings, and for the squalor and poverty of its inhabitants, namely Alaska and St. Mary's Streets and the numerous courts and alleys immediately adjacent.

Although no satisfactory history of this case could be obtained, owing to the patient's semi-delirious condition, still, judging from his symptoms, he must have been suffering between five and six days before he was brought to the institution.

The patient was decidedly emaciated; his tongue was of a brown dusky hue, but red at its tip; the teeth were covered with sordes, and the breath was peculiarly offensive. The chest and lateral aspect of the body as well as the lower portions of the thighs were quite thickly covered with the characteristic eruption of typhus. The urine was scanty and high colored, and voided with much difficulty; the bowels were loose, and of a fetid character, a condition in the writer's experience almost as common as that of constipation. The temperature, as in all cases of this epidemic, was exceedingly high, it being at the time of his admission 105⅘°. The delirium was of a low, muttering type, and continued so until the beginning of the third week, and indeed it may here be remarked that this is the characteristic delirium of the disease, the busy, violent delirium being rarely seen.

The writer has left to the last what, in his opinion, was one of the most, if not the most valuable diagnostic symptom of the disease, namely, muscular and osseous hyperæsthesia and tenderness on pressure; for no matter in what condition of comatose insensibility was the patient, cries of pain could readily be elicited by even slight pressure over the tibia, ulna, humerus, or any of the subcutaneous bones.

The peculiar typhus odor from the skin and breath, referred to by some authors as so characteristic of the disease, is, in the writer's opinion, of but little value, it often being entirely absent, as was the case with this patient, and when present was in no way distinguishable from the ordinary smell of the sick ward, and the writer may also add in this connection that the characteristic eruption of the disease lends but little diagnostic aid to the practitioner, both on account of its frequent absence, and from the protracted delay in making its appearance, and as proof of this would cite the nineteen cases of his own, in which but ten showed any eruption whatever, and in two of these the eruption did not make its appearance until the eighth day of the disease. In the cases treated by my colleagues, above referred to, the eruption was as frequently absent or protracted in its appearance as in those here recorded.

The patient remained in the condition described until the fifteenth day of the disease, or nine days after his admission, when convalescence commenced, the fever and delirium lessening, diarrhœa becoming checked, the tongue cleaning up, and strength returning.

It may be here remarked that the overwhelming muscular prostration attending the cases constitutes one of the most important factors of the disease, and is even greater than that which attends typhoid, although convalescence takes place with much greater rapidity in typhus.

At the beginning of the fourth week the man was able to move about the ward, still quite weak. A few days later he was sent to the convalescent ward, cured.

Case II.—J. J——, colored, aged sixty, admitted to the hospital March 7, 1883. This case is of interest principally on account of its rapidily fatal termination; the patient having died thirty-six hours after his admission.

The history of this case, like the former, was very unsatisfactory; the ambulance doctor being unable to learn anything from the sick man's drunken and bestial companions. (It may be remarked, *en passant*, that there were no less than twenty-eight human beings living in a three-story wooden boarding-house in Alaska Street, from whence he was brought). However, in the opinion of Dr. Bruen and the writer, it was one of those fulminating cases of typhus fever, which afterward proved by no means of rare occurrence during this epidemic.

The man was in a completely comatose condition, and could only be aroused for a moment by pressure on the extremities; the tongue and teeth were in the usual condition found in these cases; the pulse hard and very rapid, showing 135 beats per minute; the temperature the highest of any case that came under my observation, the thermometer 106⅘°; and finally, on examination of the bladder, it was found to be greatly distended with urine, which necessitated the use of the catheter; the operation having to be repeated when necessary up to the time of the patient's death. This retention of urine was found to be generally diagnostic of a very severe case, it having occurred in every fatal instance.

On post-mortem examination the viscera were found to be congested, but otherwise in a normal condition; this condition was particularly noticeable with the kidneys. The intestines were carefully examined, and no point of ulceration could anywhere be detected, but the peculiar and *characteristic* "shaven beard" appearance of the mucous membrane was noticed in spots throughout the whole length of the ilium. The precise nature and microscopical anatomy of this morbid condition has not to my knowledge been definitely described by pathologists, but the practical fact remains that it was noticed in every instance in which a post-mortem examination was held.

Case III.—J. M——, white, aged fifty-five, admitted to the typhus ward March 24, 1883. This patient was recently convalescent from a severe attack of facial erysipelas in one of the wards of the hospital when stricken with typhus fever.

His condition from the onset was grave, the fever being ushered in with a series of severe chills, and intense nausea; the latter symptom continuing for the first thirty-six hours of the disease. All the symptoms of typhus were well developed in this case; the eruption appearing quite copiously on the fifth day.

Nothing beyond the persistent nausea was noticed which would invest this case with any particular interest. Death ensued on the eighth day. The autopsy revealed precisely the same pathological conditions as seen in Case II.

Cases IV. and V.—John J——, thirty-eight years of age, and Wm. J——, thirty years of age, both white. They were admitted to the hospital on the same day, and were brought from the same house on Alaska Street.

They both gave as a history of their cases a feeling of great lassitude, weariness, and a condition of general malaise for several days prior to the attack, and the man J. J—— had a severe chill while being conveyed to the

hospital in the ambulance. The eruption did not appear in the first case until the seventh day, and was then so slight as to be recognized with much difficulty, while in the second patient there was no perceptible eruption whatever.

It is a curious fact, but one well borne out by the writer's experience in this epidemic, that in these cases in which the eruption was slight or altogether absent the temperature and all other symptoms were increased in severity. This fact was well illustrated in these two cases, in which all symptoms were of the gravest character. Constipation was marked in the first case, but the bowels were rather loose than otherwise in the second.

The second case died on the ninth day in a state of complete coma; the first, however, recovered after a protracted illness and a tedious and slow convalescence.

The autopsy held on the second case revealed precisely the same morbid conditions as in Cases II. and III.

Case VI.—John L——, sixty-five years of age, white, admitted to the hospital March 30, 1883. This patient was also brought from the same infected locality as the preceding ones. There was at the time of his admission a slight typhus eruption scattered over the trunk, which increased greatly in the next twenty four hours, and turned to a dark black color a few hours before his death. The thermometer showed a temperature of 104⅕°, the significant brown tongue and an unusual degree of hyperæsthesia of the muscles and bones were present, with extreme prostration and low delirium. He lingered in this condition for two days, when he died.

On post-mortem examination the viscera were found to be more than usually congested, especially the lungs. The same pathological changes were found in the intestines as in the preceding cases.

Case VII.—Thomas R——, twenty-eight years of age, white, admitted April 2d. The diagnosis of this case was for a time involved in some doubt, as in its early course it closely resembled typhoid fever, but the appearance of the eruption on the fifth day, the peculiar brown tongue before described, and the muscular hyperæsthesia, made the diagnosis at that time positive. The attack was comparatively light, the temperature never reaching over 102½°; the muscular hyperæsthesia being not so well marked as in graver cases, and the patient being able to be aroused from his stupor from time to time.

Convalescence set in toward the end of the third week, and complete recovery quickly ensued. The return to health and strength, as in most cases of this disease, was quite rapid.

Cases VIII. and IX.—Charles A——, thirty-two years of age, and Joseph P——, thirty-six years of age, both colored, the former admitted March 30th, the latter March 31st. They were brought from the same shanty, situated in a small alley running off Alaska Street, and according to their own statements they were both taken sick about the same time. The first case was of that fulminating character described in a former patient, and he died in a state of complete coma on the fifth day after his admission. The retention of urine and his profound comatose insensibility almost from the onset of the attack formed the two most prominent symptoms of the case; constipation, muscular, and osseous hyperæsthesia were present in a marked degree. The autopsy revealed the usual congestion of the viscera and the "shaven-beard" appearance of the mucous membrane of the ilium. The brain was found in a normal condition, except a slight increase in the "puncta vasculosa."

The second case was of a light character, and was analogous to Case VII. The individual was completely convalescent by the fourth week, and his subsequent recovery was rapid.

Case X.—Joseph D——, thirty-six years of age, white, admitted April 2, 1883. The patient gave a history of prostration and fever for three days prior to his entrance into the hospital. When first seen no eruption could be detected on any portion of the body, but on the fifth day of the disease, or two days after his admission, a few spots were noticed on the lower extremities; all the other symptoms of typhus fever were well marked, except, instead of constipation being present, the bowels were loose, the patient having from three to four passages daily, and the fæces being of a fetid character and of a spinach-green color; precisely similar in looks to that of Case II. There was also present from the very onset of the disease a peculiar symptom, and one not very frequently seen, namely, intense nausea and vomiting, the ejecta varying in color from a dirty brown to a pea-green. This symptom lasted without any abatement up to the time of the patient's death, which occurred forty-eight hours after his admission. The temperature was very high from the beginning, the maximum point reached by the thermometer being 105⅘°; the muscular hyperæsthesia was well marked, but the delirium and coma were not as great as we should have been led to expect from the gravity of the other symptoms. Retention of urine was also present.

On post-mortem the viscera were found to be all deeply congested. The stomach showed decided evidences of chronic gastritis, superinduced no doubt by the patient's intemperate habits. The liver was in a far advanced stage of "interstitial hepatitis." The ileum showed in many places the "shaven-beard" appearance of the mucous membrane.

Case XI.—John W——, twenty-six years of age, colored; admitted to the hospital April 7, 1883. The patient was a pauper inmate of the institution when attacked by the disease, and as an assistant attendant in the typhus wards, was directly exposed to contagion. The writer would here mention that this was by no means the only case of typhus fever which arose from contact with the sick, for the two men whose duty it was to carry the patients from the ambulance to the wards, and the dead to the dead-house, both contracted typhus fever, and one died. This patient was first seized with a well-marked chill, followed by some nausea, the temperature quickly rose, until at the beginning of the third day it reached 103⅘°. The delirium, which was at first but slight, increased in severity up to the fifth day; it was not of the usual low character, but was of the active, busy type sometimes seen in typhoid fever. The bowels were exceedingly constipated, and the urine scanty, and of a high color, containing a small amount of albumen; a condition of rare occurrence in this epidemic, not even a trace having before been detected in the twenty-seven cases whose urine the writer examined.

It is proper to state that this condition of slight albuminuria was not a constant feature even in this case; it disappeared on the eleventh day, and did not again return.

The hyperæsthesia was well marked and persistent, the pulse hard and rapid, and the tongue cracked and fissured in numerous places, of a dark brown hue with a red and angry-looking tip.

These symptoms continued with more or less severity until the thirteenth day, with exception of the temperature alone, which was reduced to 101⅘° by the sixth day, above which point it never again rose. Immediately a decided amelioration in the symptoms occurred, and by the end of the third week convalescence was fully established. Some ten days later the patient was discharged cured.

Case XII.—George H——, aged nineteen, white, admitted April 15, 1883. This was the only patient of the nineteen which fell to the writer's care (exclusive of the two which originated in the institution) which did not come from the infected locality of the city so often referred to in the preceding pages.

The patient was of respectable parentage, and as far as could be determined was under good sanitary and hygienic surroundings prior to his attack. His illness dated about four days prior to his admission to the hospital,

and was attended by a physician in the northern section of the city, who recognized the nature of the case and by whose advice he was sent to the hospital. When first seen he was in a state of profound coma; the eruption, although not abundant, was still quite noticeable on the abdomen and lower extremities; the hyperæsthesia of the muscles quite distinct; the pulse rapid, but weak and feeble, and the temperature registered 104⅘°. The breath was very fetid, the teeth covered with sordes, the tongue dry, cracked, and of the usual dark brown hue almost to the tip. The bowels were costive, and the urine had to be drawn off by the catheter.

The patient rapidly and progressively grew worse, the coma deepened, the respiration became more and more shallow, the heart's action more feeble, and death finally occurred some thirty hours after his admission.

The autopsy revealed deep congestion of all the viscera, particularly of the lungs and kidneys, and the characteristic pathological appearances were noticed in the ilium. The condition of the brain was normal, except a slight increase of the "puncta vasculosa." The cerebro-spinal fluid was about normal in quantity.

Case XIII.—George A——, aged forty, white, admitted April 26th. A pauper inmate of the out-wards of the Almshouse, who, as far as could be learned, had not been directly exposed to contagion. His case proved to be of a lighter type than usually seen during this epidemic, and although all the symptoms of typhus fever were present, still they were all of a mild degree. The eruption occurred late, and was very light. He became convalescent about the fourth week and soon after was discharged cured.

Case XIV.—Thomas McG——, aged fifty-one, white, admitted May 3d. No history of this case could be obtained from the patient, owing to his condition, but his friends living in the locality from which he was brought (Seventh and St. Mary's Streets) told the ambulance doctor that he had been in the condition in which he then was nearly three days. This case differed in no respect from other severe ones of the epidemic, except that the fever was protracted to the end of the fourth week, and convalescence was extremely slow, it being nearly two months before he was able to walk even a short distance unassisted. Diarrhœa was present up to the end of the third week.

Case XV.—Charles S——, aged forty-three, white, admitted May 21st. The disease as in many others cases during this epidemic was ushered in with a severe chill. The temperature arose on the third day to 103⅘°, and remained at that point until the fifth day, when for one day it slightly declined. The pulse was hard and rapid, registering with but little variation about 138 beats per minute. The delirium was of a more violent type than usual, and continued so up to the time of his death. The urine was scanty and high colored, rich in urea and the urates, a few tube casts being also noticed. The bowels were rather loose, and the fæces of a dark green color and very fetid. The eruption, which was quite copious, made its appearance on the fifth day. The exhaustion and debility of the patient was very marked, and the emaciation was undoubtedly greater than presented by any other case of the epidemic; this might be accounted for by the exhausted constitution of the patient prior to the inception of the disease.

After the fifth day the man began rapidly to grow weaker and weaker, the stomach rejected both food and medicine, except in the minutest quantities, and the temperature, despite all remedies, remained at 105°. He died on the ninth day in a state of complete coma.

On post-mortem examination the viscera, as in the other cases, showed evidences of deep congestion; the intestines revealed the characteristic "shaved beard" appearance of the mucous membrane; the kidneys were far advanced in parenchymatous nephritis, and the brain, beyond a slight superficial congestion, showed no abnormality.

Cases XVI. and XVII.—Patrick S—— and Michael McG——, aged respectively thirty-nine and twenty-eight, white, both admitted May 26, 1883. Both cases, as far as could be ascertained, were taken ill about the same day, and were brought from the vicinity of Sixth and Lombard Streets. The eruption appeared in both men on the seventh day, quite plentifully in the first patient, but rather scanty in the second; the temperature was never very high in either—the maximum being 102.⅘°; the delirium was not marked, and by the twelfth day their intellects were perfectly clear. The bowels in each were inclined to constipation. At the end of the fourth week convalescence was fully established, and soon after they were discharged cured.

Cases XVIII. and XIX.—Nothing of particular interest was noticed in either case, all the symptoms being well developed, but of a light type. Recovery occurred in both cases toward the end of the fourth week.

The writer has postponed a recapitulation of the treatment of the cases presented in this epidemic until the symptoms and pathological conditions of each could be given in detail; for the treatment pursued, with but few exceptions to meet certain emergencies, being well-nigh similar, it would be a work of supererogation to state it *in extenso* in each case.

From the very commencement it was found necessary to stimulate and support the patient, attention at the same time being given to the secretions, and means taken to arrest hyperpyrexia and hold in check excessive delirium. Free stimulation with whiskey or brandy, preferably the former was necessary from the onset, and the amount required was found to be about one ounce every three hours for the first three days, and subsequently increased by giving the same quantity every two hours, and as convalescence became assured the interval was again lengthened. There can be no doubt that our chief remedial agent in this epidemic was alcohol, and without its use the mortality would have been greatly increased.

Much attention was paid to the administration of easily digested and nourishing food. A strict adherence to a liquid dietary is not necessary, indeed occasional indulgence in easily assimilated solid food is not only beneficial but strongly indicated. Milk, eggs, strong animal broths, arrowroot, rice, etc., were administered with regularity, the patient taking nourishment in some form every two hours by day, and three hours by night, even arousing him from sleep for the purpose. Small amounts of solid food, as finely chopped sweetbread, rare tender beef, or chicken, were occasionally given, but care was exercised that nourishment, whether liquid or solid, was taken only in small quantities at one time.

Aconite and veratrum viride have been recommended by some authorities as the most useful and potent remedies we possess for the excessive hyperpyrexia, and although the writer does not for a moment deny the wonderful power of these two agents in controlling cardiac action and reducing the temperature of the body, nevertheless in his experience they have both proven entirely too depressing in their action for a disease of this character. The use of quinine in ten-grain doses four times daily, along with the following prescription, is attended with much more beneficial results:

℞. Tincturæ digitalis..... f℥ ij.
Spts. æther. nit..... f℥ jss.
Liq. potass. cit.,
Liq. ammon. acetat.....āā f℥ ji.
Aquæ.....q. s. ad f℥ vj.
M. Fiat mistura. Sig.—Tablespoonful every three hours.

These remedies along with frequent sponging with cool water, a small amount of vinegar or bay rum being added, seldom failed in the experience of the writer to reduce the highest temperatures.

Some authors have recommended in cases of great and persistent hyperpyrexia the immersion of the patient in a

cold bath ; but this is, to say the least, a practice attended with the greatest danger, and should only be resorted to in the most desperate cases, and then only when all other means have been tried and failed. The writer employed the cold bath treatment but in one case, and then only used it after having tried all other remedies without avail. The beneficial effects of the bath were very transient ; a reduction of 2½° having occurred immediately after the immersion, but scarcely had a half hour elapsed before the thermometer registered ½° higher than before the bath. The operation was, however, repeated, but with the same unsatisfactory results.

Chlorine water was extensively employed by Dr. Ludlow in his cases, but with no very encouraging results, although in a few instances it was claimed that considerable benefit was derived from its use. It is an old remedy for the disease, and was originally brought forward on account of its supposed specific effects ; but the history of this epidemic, as well as those which have preceded it, conclusively prove that there is no specific for typhus ; or in other words, therapeutists have not yet discovered any article that may be considered directly antagonistic to the disease. The sulphites have also been employed as supposed specifics, but with the same results. Chloral and bromide of potassium, in a mixture containing ten grains of the former to twenty grains of the latter, proved very efficacious in abating the delirium when active and exhaustive to the patient. The writer exclusively used a combination of the oleoresin of lupulina, ℥ xv., and the tincture of cannabis indica, ℥ xx., for such cases, and can testify to its great utility. Belladonna is also strongly recommended by some authors, and is particularly advantageous in those cases characterized by low muttering delirium. Opium should, as far as possible, be avoided in all cases. If constipation is persistent, an occasional laxative should be employed, and the writer knows of none which so well answers the purpose as the ordinary sulphate of magnesia, or Epsom salts. The use of the mineral acids, especially nitro-muriatic, in ten-minim doses is possibly of some utility, and may be combined with the quinine treatment referred to above. If, as sometimes occurs, the kidneys cease to excrete the proper amount of urea, and as a consequence uræmic coma is threatened, sinapisms over the renal region, and vesication of the nucha are called for.

Bed-sores, which frequently occur during the course of the disease, are beneficially treated at first by a lotion of alcohol and alum, but when fully developed carbolized oil is best used instead.

In view of the contagious character of the disease, typhus cases should not be treated in hospital wards with other patients. If overcrowding be prevented and free ventilation secured, the fever miasm is not as easily generated, nor is the disease as likely to be communicated. Extreme cleanliness, both of the patient and the wards, along with the free use of disinfectants, such as carbolic acid and chlorinated lime, are hygienic measures of great importance.

Mortality.—Although the average mortality is generally placed at from eighteen per cent. to twenty-five per cent., in this epidemic it reached at least thirty-three per cent., but as age greatly modifies both the prognosis and mortality (the disease not being a very fatal one before the twentieth year), and as seventy-five per cent. of all our cases were between thirty and thirty-five years old, and many ranged between forty-five and fifty-five, a very important factor in increasing the mortality of this epidemic was thus produced. It is also but just to say that at least nine-tenths of all our patients were persons debilitated and exhausted by every vice, and most of them exposed from childhood to most unhygienic surroundings.

Chemical Euphemism.—Few people are aware, or seriously consider that when they take a cup of tea it is essentially an aqueous solution of trimethylxanthine ($C_8H_{10}N_4O_2$) which they are drinking.

CEREBRAL LOCALIZATION—THE CENTRES FOR VISION.

By PHILIP ZENNER, A.M., M.D.,

CINCINNATI, O.

(Continued from p. 235.)

Pathological data.—Our investigations in this third line of research will not lead us to as exact results as either our anatomical or physiological studies. But they are, nevertheless, the most valuable in promoting the main object we have in view, cerebral localization in man, and are quite sufficient to arrive at definite results.

Impairment of vision may be caused by lesions of any part of the intracranial visual apparatus, or by lesions of indifferent portions of the brain, as optic neuritis so frequently attends any coarse cerebral disease. But as we are seeking for the centre of vision in the cerebral hemispheres, visual disturbances will only interest us where they appear to be directly produced by lesions of limited portions of the hemispheres. To obtain such cases we must be able to eliminate general causes, as, for instance, optic neuritis, dependent upon increased intracranial pressure, and the visual symptoms produced by involvement of the more peripheral parts of the visual apparatus, the optic nerves, chiasma, and tracts, and the basal ganglia, optic thalami, corpora quadrigemina, and geniculate bodies.

A number of such cases have been reported. In all of them there was disease of the occipital lobes, the part which we have already been taught to consider the chief, if not the only seat of the centre for vision.[1] In all of these cases the same kind of disturbance of vision was found, loss or impairment of vision on one side, homonymous lateral hemianopia.[2]

As this symptom is so important for us in this connection, we will dwell briefly upon it. There is an obscuration or entire defect of one-half, or approaching one-half, of the field of vision, due to a loss of sensibility on the corresponding sides of both retinæ. Lesions of one hemisphere cause loss of sensibility of the retinæ on the same side, and blindness in the field of vision of the opposite side. Thus a lesion in the left occipital lobe is attended by paralysis of the left half of each retina, and blindness of the right half of the field of vision, or right hemianopia. It is to be remembered then, when we say right or left hemianopia, we are describing the side on which the patient does not see, and that it betokens disease of the opposite side of the brain.

Of the cases of disease of a cerebral hemisphere with accompanying hemianopia some cannot be utilized for our present purposes for reasons already mentioned, because the disease is very extensive, and especially because it involves the basal ganglia,[3] or because there were at the same time changes in the optic nerves ;[4] others, because the lesion was of too recent date,[5] or because the examination was not made with sufficient exactness, or, at least, was not sufficiently detailed in the report.[6]

We will proceed to the mention of the individual cases which can be utilized in the present investigation. Each one will be given as briefly as is consistent with our present object.

In a case of Baumgartner [7] a complete left hemianopia appeared suddenly and remained until death. The post-mortem examination revealed "an old apoplectic cyst,

---

[1] There is, so far as I know, but one apparent exception to this statement, a case of Hugenin (Ziemssen, xi., p. 816), where a lesion was found only in the anterior part of the parietal lobe. But as the disease extended into the subcortical medullary matter it probably reached to the optic radiations.

[2] The terms hemiopia, hemianopia, and hemianopsia are all used to express the same condition. The oldest one, hemiopia, is becoming less and less used. The term hemianopia will be alone used in this paper.

[7] Centralblatt f. d. Med. Wissenschaften, 1878, p. 369.

the size of a walnut, in the right occipital lobe. Its inferior wall was separated from the cavity of the right posterior cornua by a layer of healthy tissue several millimetres in thickness. The superior wall was formed by the three occipital convolutions, which were altogether softened. There was also a focus of softening, the size of a pea, in the roof of the left anterior cornua, and an apoplectic cicatrix, scarcely half the size of a lentil seed, in the centre of the right thalamus. Optic nerves, tracts, and chiasma, and geniculate bodies and corpora quadrigemina were normal." The lesions in the thalamus and anterior cornua may be ignored, as we know they could not have produced the symptoms. We need not, therefore, hesitate to conclude that the hemianopia was here due to the disease in the occipital lobe.

A case of Westphal [1] had occasional attacks of unilateral convulsions for a number of years before death. He had also a complete left hemianopia. The post-mortem examination revealed a focus of softening in the right occipital lobe, which extended into the parietal lobe and the bordering temporal convolution. The softening was in the medullary substance, the cortex being unaffected. The motor regions of the hemispheres, the internal capsules, large ganglia, and optic tracts were normal.

In a man of seventy-two, reported by Marchand,[2] with complete left hemianopia and hemiplegia there were found destructive changes in the occipital lobe, and also a degree of softening of the cortex in parts between the occipital lobe and the fissure of Rolando.

In Curschman's [3] case there was complete left hemianopia without other cerebral symptoms. Post-mortem examination revealed "a large focus of softening in the right occipital lobe, which reached to the surface, chiefly in the superior surface and apex of this lobe." Rest of brain normal.

In a case of Haab [4] a woman of sixty-one, had complete left hemianopia, with scarcely any other cerebral symptom, for one year before her death. On post-mortem examination there was found softening of the right occipital lobe, especially its median surface. The cortex was chiefly affected, but the softening extended deeply into the medullary substance, though it did not reach as far as the posterior cornua.

The foregoing cases prove that hemianopia may be produced by disease of the hemispheres which does not involve the primary visual centres (optic thalami, geniculate bodies, and corpora quadrigemina) or the more peripheral visual apparatus. They prove also that this symptom is caused by disease of the cerebral cortex. For, though in all of these instances the subcortical medullary substance was affected, we know that nerve-fibres are not centres for functions, that they merely serve to convey impressions and impulses; and that, therefore, in the above instances their involvement could only have produced symptoms through cutting off the communication with the cortex.

The cortex, then, is the centre for sight. But to what part of the cortex this function belongs is not so definitely answered by these instances, for we cannot say to just what extent the symptom was here due to destruction of the white subcortical substance, nor do we know in exactly what area of the cortex the destroyed fibres found their final distribution. But as in these instances the disease was chiefly or entirely in the posterior parts of the hemispheres, it is rendered probable from them that the cortical visual centre is in the posterior part of the brain. This conclusion is further corroborated by other and more striking instances. But before considering the latter we will briefly mention a few reported cases which, though less convincing than those just given, still have some weight in the above conclusion.

In a case of Stenger,[1] with occasional left-sided convulsions, temporary left hemiplegia, and left hemianopia, which remained permanently during the last six months of life, there was found, in addition to an internal hydrocephalus and slight general charges in the brain, decided lesions in the right occipital and parietal lobes.

In a second case of Stenger [2] there were occasional unilateral convulsions, right hemianopia, first observed four months before death and remaining permanently, and about one month before death also a left hemianopia, so that the patient was now completely blind. The post-mortem examination revealed slight general changes both in the meninges and in the brain, and decided atrophy of both occipital lobes, that in the left being apparently of older date.

In both of these instances the general changes in the brain, as well as the clinical histories, were like those of general paralysis. But inasmuch as in general paralysis the pathological changes are usually slight, and the localizing symptoms slight and transitory, and in the above instances the visual defect was both complete and lasting, and the only decided lesions those in the parts mentioned, it is highly probable that these lesions and symptoms were in direct relation with each other.

In a case of Wernicke,[3] there was, in addition to certain disturbances of speech, a right hemianopia, which existed for twenty months before death. There was found extensive disease of the left hemisphere. The rest of the brain appeared to be normal excepting that a part of the left corpus striatum was softened, and the optic thalamus seemed a little reduced in size.

The lesion in the corpus striatum could not have produced hemianopia, and the changes in the thalamus were apparently too trivial to account for the visual disturbance.

In Nothnagel's [4] case there was right hemianopia and extensive destruction of the cortex of the left occipital lobe. But there were also motor symptoms and lesions in the anterior parts of the brain, so that the observation has only a problematic value.

In a case of Jastrowitz,[5] with right hemianopia (fundi oculi normal), a large part of the posterior part of the left hemisphere was destroyed by a tumor, which reached to the level of, but did not implicate, the optic thalamus. The rest of the brain, ganglia at base, optic tracts, etc., was normal.

There might be some hesitancy in admitting this case as evidence, because of a tumor which usually produces general symptoms, symptoms due to increased intracranial pressure. But hemianopia is a symptom of such local significance, and there is nothing to explain it in this case but the local lesion, so that this case has probably as much value as those just preceding it.

The five cases just given, notwithstanding the impossibility of definite conclusions where each one is critically examined by itself, have still, when taken together, a certain value in the solution of our problem.

Of far more value, perhaps the most valuable of those yet recorded, is the case to be now mentioned, the second one of Westphal, reported in the *Charité Annalen*, 1882.[6] In this case there was, in addition to occasional right unilateral convulsions and disturbances of speech, an impairment of the muscular sense in the right arm and hand, and a right hemianopia, which existed from the time of the first observation, October, 1879, to the time of death, December, 1881. There was found, post mortem, disease of the cortex over the greater part of the occipital lobe, the parietal lobe, including the posterior central convolution, and a small part of the temporal lobe. The disease did not extend into the subcortical medullary substance.

This case proves, what we had already concluded from previous cases, that there is a visual centre in the cortex. As regards its exact localization it does not lead us beyond our former conclusions, that the visual centre is in the posterior part of the hemispheres.

I will next mention two cases in which hemianopia followed traumatic injury of the brain.

The first case was a man, aged twenty-three, wounded at the battle of Antietam. According to the account of Surgeon McCall,[1] the ball passed from about one inch above the occipital protuberance into the cavity of the cranium and emerged at a point to the left of the median line about an inch and three-quarters from the point of entry. There was temporary paralysis of right arm and leg. Keen and Thompson[2] made a careful examination eight years after the injury. Fundi oculi were normal. Central vision, and vision in left half of field were normal, while in the right of the field of vision there was complete blindness. The blind field reached to a vertical line passing through the point of fixation. Only at the latter point there appeared to be a very slight bending of the line toward the affected side.

Nieden[3] reported the following interesting case, which, at the time of his last report, in the latter part of 1883, was still under observation. A young woman of twenty-two sustained a severe injury in the occipital region from a fall. Notwithstanding the continuance of headache and slight paralytic symptoms, she attended to her ordinary household duties until about seven months after the injury, when, on account of the supervention of serious symptoms, mental disturbance, convulsions, etc, operative interference was resorted to. There was at this time slight paralysis of the right arm and leg, but vision, which had been repeatedly and carefully examined, was altogether normal. The trephine was applied, and a button of bone removed, just to the left of the sagittal suture, and one-half centimetre above the external occipital protuberance.

This, according to the calculation of Nieden, was just over the apex of the occipital lobe. During the operation the dura mater was injured and subsequently brain-substance protruded through the opening in the bone.

The second day after the operation it was noted that the paralysis and anæsthesia of the arm were diminished, but that the patient spoke of a cloud before the eyes, especially on the right side. Subsequently the patient entirely recovered from the paralysis, headache, etc., but the disturbance of vision remained permanently. As soon as a careful examination could be made it was noted that in the right eye the whole of the temporal field of vision and a part of the upper median field were missing, and that central vision was impaired. In the left eye central vision was perfect, but there was a slight concentric contraction of the field. A year subsequent to the time of injury central vision in the left eye was still perfect, but one-third of its median field was missing. This was attributed to the cicatrization of the wound in the occipital lobe causing further destructive changes in a part of that lobe which had hitherto functioned for the inner part of the left retina.

Though no post-mortem examination was made there could scarcely be better evidence of cerebral localization than this case. The impairment of vision was the immediate result of an injury of the surface of the brain, in just that locality where such a result might be expected. But, besides that, the visual disturbance followed the injury immediately, no other cerebral symptoms appeared, in fact, those previously existing began immediately to disappear, so that the visual symptoms cannot be attributed to any general injury or involvement of distant parts, but is a direct expression of local changes.

The last three cases are almost positive proof of the general conclusion above drawn, that there is a cortical centre for vision which is situated in the post part of the hemispheres. When these observations in man are compared with experimental results in animals, we may state that the visual centre is mainly in the occipital lobes.

I shall add but one case to the foregoing, which, on account of the theoretical and practical value, will be given somewhat in detail.[1] A man of forty-five suffered in March, 1881, with severe headache in the left occipital region, and observed also that he did not see objects on the right of the field of vision. A careful examination, in July, revealed a right hemianopia nearly to the median line, and normal fundi oculi. At this time there was no other cerebral symptom of local significance, but shortly afterward an awkwardness in the use of the right extremities was observed. There was also observed impairment of the cutaneous sensibility, muscular sense and muscular power of the right extremities. At first these were more marked in the leg, but they gradually increased in both arm and leg, until these functions became entirely abolished. August 1st, slight paralysis of the muscles supplied by the lower branch of the right seventh nerve was observed.

From the above symptoms and the presence of fever, emaciation, etc., a brain abscess was diagnosed, and, August 3d, the abscess was opened. The trephine was applied at a locality supposed to correspond to the posterior superior angle of the left parietal bone. About an ounce and a half of pus escaped after an incision into the brain. For some days there was improvement, diminution of paralysis, etc., but patient died August 16th.

Post-mortem examination revealed what Wernicke described as a tubercular abscess of the brain. The abscess was of the size of a large hen's egg, and occupied the left occipital and parietal lobes, occupying rather the median than external portion of the parietal lobe.

The lesion here found in itself might be of no more localizing value for the symptom hemianopia than several of those already mentioned, merely indicating that hemianopia was dependent upon disease of a hemisphere. But taken in consideration with the development of the symptoms and other facts in cerebral localization the case is more significant. There was a gradual development of the symptoms, first hemianopia and then gradual involvement of the leg, arm, and face. Now the centres for the muscles of the leg, arm, and face lie respectively more and more distant from what we have taken to be the centre for vision. So the development of the symptoms seem to demand the following explanation: the abscess began in the occipital lobe, causing only disturbance of vision, and as it extended forward it gradually involved the centres for the leg, arm, and face.

It may be permitted to add a word of admiration for the boldness of applying to practice the principles gained from scientific study. Although operative interference was without avail in this case, it may, nevertheless lead to its more successful issue in the future.

This closes the pathological material at our command for the establishment of a cerebral centre of vision in man. The cases are few in number, partly because those instances are rare where such circumscribed lesions occur, partly because careful examinations during life are usually not made, have scarcely been made at all until recent years. More than one-half of the above cases were reported within the last three years.

A proper examination for the symptoms is more important than is usually believed. Patients very frequently do not observe visual disturbances when they are only partial, or they falsely interpret them, for instance, say that they do not see with the left eye, when there is left hemianopia. Physicians also frequently overlook these symptoms, and blunders have been made by skilled specialists which were only rectified by careful periscopic examinations.

We have now done with the evidence, gained from the

[1] Wernicke and Hahn (Virchow's Archiv., 1882, xxxvii., 2).

study of anatomical, physiological, and pathological data, which bears on the question of the cerebral centres of vision. We have seen that all points alike to the presence of such a centre in the cortex of the posterior portion of the hemispheres. It may be that other parts of the brain are in some manner connected with the sense of vision, for the subject is not entirely cleared up. But it must be accepted as an acquired fact in anthropological science that the sense of vision is intimately connected with a limited portion of the cerebral cortex.

A CASE OF POISONING BY PODOPHYLLUM PELTATUM.

By WALTER B. REYNOLDS, M.D.,

WASHINGTON, D.C.

The following case is presented to the profession with the belief that it is of sufficiently rare occurrence to make it of some interest to them, as well as being worthy of record.

About 1 P.M., on the 9th of June last, I was summoned to come at once to see Mrs. C——, who was said to have been taken suddenly and critically ill. On reaching the patient I found her with the following symptoms, to wit: incessant retching; scant, but very frequent bloody stools; violent colic and tenesmus; eyes sensitive to light, and pupils slightly contracted; skin and extremities cold; slight indications of respiratory paralysis; pulse rapid and weak, and other usual symptoms of collapse. She was considerably excited, but perfectly conscious, and stated that she had been feeling badly for several weeks on account of chilly sensations and the irregularity of her bowels. To remedy these troubles she had taken, the evening before, three of Dr. Jayne's liver pills, to which she attributed her illness. She denied having taken anything else, but mentioned, in reply to a question, that she had not had her sickness for six weeks. Nor had she suffered from any of the early symptoms of gestation. Brandy and fomentations were the domestic remedies that had been used.

I had her head lowered, applied external warmth, with a large sinapism over her abdomen, and gave a hot brandy punch (which was repeated every half hour) just as soon as she ceased retching, which had returned shortly after my arrival. The matter vomited consisted of bile and glairy mucus, each in a small quantity. The punch was retained, and together with the external warmth caused, in a short time, her skin to become somewhat warmer, and she expressed herself as feeling more comfortable; but she still had frequent paroxysms of great pain. To relieve this I endeavored to administer a hypodermic injection of sulphate of morphia, and also brandy, but my syringe could not be made to work. As the patient had been almost constantly vomiting and purging since 2 A.M., neither an emetic nor cathartic were considered necessary. A messenger having returned from the drug store, I placed on her tongue one powder of the following formula:

℞. Bismuth. subnit..... 6.00 grm.
Pulv. ipecac. comp..... 2.00 grm.

M. Ft. chts. no. vj.

Sig.—One every half hour until two have been taken, and then repeat hourly.

A warm starch enema was also given, and repeated after an interval of two hours. The patient was to use a bed-pan, and to be kept as quiet as possible. After remaining awhile I left, giving instructions that I should be sent for in case any change occurred, and that I would return later.

At 6 P.M. Mrs. C—— was somewhat easier. Her bowels continued to move frequently, and were still melænatic in character, but did not occasion as much pain. Her pulse was 90, a little stronger, but irregular. Retching had ceased. She considered herself stronger, but complained of difficulty in breathing, and had suppression of urine. The punch was made stronger (32 grm. instead of 16 grm. of brandy to a tumbler of milk), and ordered to be given, in the form of milk punch, a tablespoonful every fifteen or twenty minutes until the distress in breathing had improved, as I noticed it was not so great for awhile after the stimulant had been taken. The powders were continued every two hours. Warm cloths were applied over the hypogastric region, and renewed every two hours, with a wineglassful of flax-seed tea every three or four hours. Her diet to consist of milk, weak tea, and two soft boiled eggs in case she desired anything to eat.

Her husband was present at this visit, and I elicited the following facts, which confirmed my suspicion that his wife had taken an excessive dose of one of the drastic cathartics. At the suggestion of a lady neighbor she purchased the previous day two May-apples (weighing 16 grm.), one of which she steeped for an hour in half a pint of boiling water; all of which she drank warm, after straining it, on retiring at 10 P.M., the 8th. Mrs. C—— is a healthy, tall, well-developed German woman, about twenty-five years of age, and the mother of three living children.

On the morning of the 10th she was very much improved. However, she slept very little during the night, owing to continued hypercatharsis, which had occurred about every three hours since my last visit. Her pulse was 85, and stronger, but still irregular. She suffered with comparatively little pain, and while it continued to return periodically, yet the intervals were gradually being lengthened. Complained of general weakness and soreness, with a feeling throughout the digestive tract as if she "had swallowed boiling water." She had to discontinue the milk punch, as it produced retching, but took instead brandy and water at the hours ordered. The powders were continued every three hours; also flax-seed tea every two hours. Warm applications were constantly kept over the abdomen, for their soothing effect, her urine being passed in the normal quantity. The other treatment was continued, with the exception of the brandy, which was allowed only three times daily, as no difficulty of breathing was experienced.

The following morning I found that the patient had had a good night's rest, and no movement of the bowels nor pain since 5 P.M., the previous day. Said she relished her breakfast, and felt well enough to be up if she were not so sore and weak. There was no symptom of salivation at any stage of her case, as has generally occurred in experiments with this medicine, especially on the lower animals. I gave directions for her to remain quietly in bed for a few days; to take beef-tea in addition to her other diet, with one powder twice, and brandy (16 grm.) three times daily. Flax-seed tea every three or four hours.

Three days later I called, and found Mrs. C—— attending to her household duties. She had steadily improved, and I did not detect any irregularity in her pulse, though it was still weaker and faster than normal. She looked pale, and said she felt weak, but in all other respects thought herself better than she was before taking the May-apple. I cautioned her in regard to diet; stopped the powders, but continued the brandy twice daily. I ordered the following:

℞. Tinct. ferri chlor..... 24.00 c.c.
Quiniæ sulph..... 4.00 grm.
Strichniæ sulph..... 0.03 grm.
Syr. aurantii flor..... 48.00 c.c.
Aquæ.....q. s. ad. 128.00 c.c.

M. Ft. sol. Sig.—A teaspoonful in a tablespoonful of water morning and night, through a quill.

No. 1522 Connecticut Avenue.

HYSTERIA IN THE MALE.

By SPENCER M. FREE, A.M., M.D.,

PHYSICIAN TO NORTHWESTERN MINING AND EXCHANGE COMPANY.

HAVING read in several recent journals reports of hysteria in the male subject, I present my experience, hoping it may be of value in helping others to avoid the errors which I made.

My practice is in a mining town of about three thousand inhabitants (including children), and nearly all of them are under my care as the company's physician. I have hence seen many cases of this disease, but only four in the male in my own practice, and one in consultation. This makes my proportion of cases one male to about fifty female, instead of one to twenty as recorded by Briquet.

I shall relate one case *in full*, as it illustrates clearly the disease as well as the mistakes of diagnosis.

CASE I.—June 20, 1882, I was called to see L. T——, adult, single, laborer, generally in the woods or on the farm; weight, one hundred and sixty-five pounds. He had always been well. Had been suddenly attacked with diarrhœa and slight vomiting. Diagnosed, "summer diarrhœa." Treatment caused improvement for a few days, when a second attack occurred. He again improved until June 29th, when he was "taken with" headache. The pain gradually extended downward along the spine, until at the end of five days the whole vertebral column was involved. Pains were paroxysmal, and at times so severe as to be alarming. There was much tenderness on pressure. The system in general showed symptoms of disease, except the temperature, which remained below 99.2°. Treatment availed very little. Occasionally he improved for a few hours. Diagnosis now made of spinal irritation or meningitis. This state of things continued until July 6th, when he was attacked with pains in the abdomen, resembling colic. He and the family said he had high fever each afternoon, and that at these times the pains were much worse. I took occasion to see him at such times, but the thermometer showed only slight increase of temperature. When the abdominal pains developed those along the spine subsided to a great extent, though they did not disappear. I became worried. I had twice made a wrong diagnosis. While thinking over the case it flashed into my mind, "Could it be hysteria?" I traced the family history for two generations, but nothing of value was found, except that some of his mother's family were "nervous" (to use her words). On the night of July 8th I was called in haste, as he was "dying." I found him apparently with severe colic. I applied hot fomentations, gave hypodermic injections of morphia, and carefully watched for hysteric symptoms. I gave him two and one-third grains of morphia in this way and a small amount of chloroform by inhalation ere he slept. (I have noted several times the large amount of morphia that hysterical patients will tolerate without producing sleep.) I noticed that he inquired for a young lady of the house, and was restless when she was out of the room; that he would not allow me to leave the bedside; and that he manifested a few other symptoms of an hysterical nature. I learned that he had proposed marriage to this young lady and had been refused. I determined, in view of all this, to treat for hysteria, and the next morning I gave him a remedy which is a favorite with me in this feigning (sham) variety, namely, a "blowing up." I began severely by telling him that nothing was the matter, that he should be ashamed of himself, that he should get up and go to work and relieve the family of this annoyance and expense, etc.

Of course he pleaded and tried to arouse my sympathy. I gave none; he then tried abusing me and berating my knowledge, I did not become angry, but continued my severity. Finally he began to swear, he sprang up in bed, clenched his fists, and prepared to "lick" me and put me out of the house. I did not flinch but looked him steadily and firmly in the eye. Suddenly he dropped "in a heap" upon the bed, was powerless, and cried and sobbed. I had conquered. After giving a few instructions as to his management I left.

He got out of his bed in a few hours (a thing which he had not done before for nearly three weeks). In two days he went to work, and has lost no time on account of sickness up to this date. I consider this a pure, unadulterated case of hysteria, and the only discoverable cause disappointment in love.

The plan of treatment here used would not be appropriate were the physician dependent upon patronage for his practice and living, as he would not be called upon again by the patient, and possibly not by the family. The ant. et potass. tartrate would probably be as effective, and not productive of harm to the one prescribing it.

CASE II.—E. L——, adult, laborer. While intoxicated he fell into a chaldron of boiling oil. After anodynes had been dispensed with he became wakeful, and soporifics had little effect. I noticed that he fancied the thermometer, and following the suggestion I impressed him with its wonderful power. He said he could feel its influence through the entire body. In from two to three minutes after placing it in the mouth, he would be asleep and remain so for several hours. I used it in this way twice a day until his death, twelve days after the accident, from perforation of the duodenum.

CASE III.—Consultation. Adult, woodsman. He had bronchitis, but was nearly well, when he suddenly "lost his voice." This condition had lasted five days when I saw him. I told him the doctor would get him an instrument, explained its effect, etc. He returned at the appointed time still speechless. The doctor placed the thermometer under his tongue, and had the pleasure of seeing him perfectly cured by one application. The disease had not returned when I heard from him more than two years afterward.

CASES IV. and V. are miners, adults, unmarried. In Case IV. the hysteria took the form of "irritable bladder." Case V. "felt funny all over," nor could we ever obtain a better description of his ailments. Both were cured (not perfectly, but satisfactorily) with placebo treatment. These cases are interesting, chiefly as illustrating the cause. The patients both masturbated to a small extent, and will probably be permanently cured by marriage.

After carefully studying the cause in all my cases, male and female, I find that in the great majority of them it is some disturbance of the sexual system or organs. This is nearly always true in the feigned variety of cases.

DAGUS MINES, ELK COUNTY, PA.,

RECTAL ETHERIZATION.—Dr. W. H. Taylor, of New Bedford, Mass., sends us the following: "Apropos of rectal etherization, I beg leave to submit the following case: On July 30, 1884, at 10 A.M., I made an attempt to close a wound of the larynx which had been produced with suicidal intent on May 15, 1884. Anæsthesia was at first induced by ether applied on a sponge over the wound. When full insensibility occurred, ether vapor was conducted into the previously washed rectum from a bottle in a water-bath at 140° F., supplied with a rubber tube eight feet in length. About four ounces of Squibb's stronger ether were given by rectum, and all entered except a few drops which had condensed in the rubber tube. The apparatus was in charge of my friend G. De N. Hough, M.D., one of the internes of Bellevue Hospital. Notwithstanding the free entrance of the vapor, the patient manifested evidences of pain during the operation, and stated subsequently that he was conscious during a large part of the time. He sat up on the afternoon of the same day, and partook of the evening meal as usual. No trouble was experienced at any time from the ether, except the failure to induce anæsthesia."

Progress of Medical Science.

Cardiopathy of the Menopause.—Under this title Dr. E. Clément writes, in the *Lyon Médical* of August 3 and 10, 1884, concerning a peculiar functional disorder of which he has had occasion to observe several examples. The patients presented all the symptoms of a profound disturbance of the cardiac functions without any physicial signs of valvular lesion. The age at which the first symptoms appeared was from forty-six to fifty years. The patients presented nothing striking in their personal or hereditary history. They were all well built, healthy women, accustomed to manual or household labor, but never exposed to excessive fatigue such as might occasion cardiac hypertrophy. Some had borne children, others had never been pregnant. There was no hysterical element in the cases, nor had any of them suffered from rheumatism. The first symptoms appeared before the menses had ceased entirely, but when they had become irregular either in their time of recurrence or in the amount of the flow. The onset was gradual. During an indeterminate period, for perhaps two or three months, the women suffered from an indefinite feeling of malaise, their strength diminished and they were less able to resist fatigue, and finally they began to suffer from palpitation. The evolution of the disease, while progressive, is yet interrupted by intervals, more or less extended, of apparent health, but each recurring attack is more severe than the preceding one. The palpitations are soon followed by dyspnœa on exertion, although there is not the slightest difficulty of breathing when at rest. Sleep, however, is often broken by distress in the region of the heart. After a time all these symptoms become very marked upon the slightest movement, and are only alleviated somewhat when the patient sits perfectly still in the chair. Another phenomenon is a feeling of faintness, which goes on sometimes to actual syncope. The examination of the heart gives a negative result. The cardiac impulse is a little exaggerated, the rhythm may be irregular, but the valvular sounds are distinct and without the faintest murmur, the first sound being somewhat the weaker. There is, however, an extreme rapidity of the heart's action, the pulse-rate being often 150 to 160 to the minute. At first there is no œdema, but after three or four attacks there may be a slight swelling about the malleoli or in the integument over the hypogastric region. Whatever may be the intensity of the cardiac symptoms, there are no bronchial nor pulmonary disturbances. The dyspnœa is entirely of cardiac origin. There is never any venous stasis, but there is an evident spasm of the arterioles. There is a remarkable pallor of the face, which is due, the author believes, to this vascular spasm rather than to anæmia. The urine is in general abundant enough, except at the height of an attack, when its excretion may be nearly suppressed; it never contains any albumen. The course of the affection is peculiar, occurring as it does in paroxysms separated by intervals of varying duration. As the disease advances the intervals of remission grow shorter. The attacks last usually about a week, but might be of longer duration were it not for medical intervention. The affection continues for an indefinite period, but the prognosis is favorable despite the apparently grave symptoms of dyspnœa, œdema, weakness, etc. The disease subsides as it began, the intervals of health growing longer and the paroxysms shorter and of less intensity. The cause, the author thinks, is to be found in a modification of innervation by the great sympathetic, and especially in excitation of the cardiac nerves. The treatment is by means of large doses of infusion of digitalis, beginning with an infusion of eight grains of the powdered leaves, and reducing gradually to five grains. Sometimes the patients acquire a disgust for this drug, and then Dr. Clément substitutes the alcoholic extract of convallaria maialis in the dose of fifteen to twenty grains. But the results are much less satisfactory than when digitalis is employed. The paroxysms of dyspnœa are best relieved by the preparations of opium, more especially morphine. At the same time, of course, the patients should remain as quiet as possible and avoid anything that may cause mental or physical disturbance.

Malarial Orchitis.—Dr. Angelo Zacco relates in the *Gazetta degli Ospitali*, Nos. 16 and 18, 1884, the case of a man who applied for relief on account of orchitis. The right testicle was swollen to three times its normal size and was painful to the touch. There was also a slight amount of epididymitis. The patient had received no injury and had never had syphilis, gonorrhœa, nor mumps. All the ordinary remedies were tried without effect, and as the patient was suffering from a mild form of intermittent fever he was given quinine. Under this treatment the swelling of the testicle rapidly subsided. The author believed that the orchitis was caused by direct action of the malarial microbe carried to the testicle in the blood stream.

Treatment of Sciatica by Congelation.—Acting upon the theory that blisters and other revulsive measures exert their therapeutic effects in sciatica through the nerve terminations, M. Debore thought to act upon a greater extent of surface and obtain a correspondingly greater benefit by congealing the integument. This he did in a number of cases by a spray of chloride of methyl, and says that the effect was marvellous. The relief to the pain was instantaneous, though there were sometimes slight relapses, which yielded at once, however, to a repetition of the congelation. The spray was directed wherever the patient experienced any pain, sometimes over quite an extensive surface. The skin was blanched temporarily and occasionally vesication was produced, but no other accidents occurred. The patients were all men and free from any suspicion of hysteria.—*Revue Médicale*, August 16, 1884.

Myasis.—Under this title Dr. Posada-Arango describes, in the *Journal de Médecine de Paris* of August 16, 1884, an affection caused by the deposition of flies' eggs in the nasal fossæ. He relates a case occurring in a farmer's boy fifteen years of age. The patient was annoyed one morning by a fly getting into his nostril, but it soon emerged and no more was thought of it. Forty-eight hours later he began to have pain in the nose, accompanied by a slight bloody discharge, and soon he noticed a worm coming from the nostril. He complained of severe headache and a noise within the head like the rumbling of carts over a stony road. Dr. Arango removed as many of the worms as he could by means of a curette, and then injected a decoction of an aromatic plant called *cordoncillo* (a sort of pepper plant), and blew tobacco fumes into the nostril. By means of these applications, frequently repeated, the nostrils were finally cleared of about one hundred and twenty worms. Of the fourteen cases of this affection hitherto reported, nine ended fatally. The fly which deposits the eggs is a little larger than the ordinary house-fly, and is of a general bluish color, though presenting a green or violet metallic hue when seen in certain lights. The worms are white, pointed at the buccal and truncated at the caudal extremity.

Acute Mania at the Menstrual Period.—Dr. Cabadé relates the case of a woman who, while menstruating, lost her husband under very terrifying circumstances. Menstruation ceased at once and did not return for eight months, during which time the patient was exceedingly nervous and suffered from slight convulsive attacks. Later she had acute maniacal attacks at each menstrual period, being perfectly sane in the intervals. The mania recurred at each monthly period, and was only controlled by large continued doses of bromide of potassium.—*Wiener Medizinische Wochenschrift*, November 29, 1884.

MEDICAL MANNERS—ANCIENT AND MODERN.

A WRITER in an English exchange laments the decadence of polite learning and punctilious manners among the medical men of to-day. Once they were very proficient classical scholars. Now, alas, a little dog Latin, *quantum sufficit* for prescription writing, is all that most of our modern luminaries possess. "Then," he continues, "if you meet some of our very old practitioners and contrast their manners with the shining lights of to day the difference will be perceived. The gracious demeanor, the courtly address, the punctilious observance of courtesy, the accuracy of phraseology, the general tone expressed in the word gentleman, are remarkable *for their absence* in the leading medical men of to-day. Brusqueness, dogmatism, self-sufficiency, brevity have taken their place. Science is accountable for this. Only half education could produce such men. Science contracts—limits the range of reading. It confines the imagination by which the soul grows. The old classical education enlarged the bounds of reading and of interest. In the old classical writers we find the almost perfection of language, and I might even say of morality."

It may be admitted that there is some truth in the criticism thus quoted. Nevertheless we are quite sure that so far as the "minor morals and manners" are concerned, a comparison of those of to-day with those of the last century will show a vast advantage to the former. In all ages there have been charges that virtue was declining. Said some one to Dr. Akenside: "Doctor, after all you have said, my opinion of the profession is this: The ancients endeavored to make it a science, and failed; the moderns, to make it a trade, and succeeded." This was in 1759, and at the present day we hear the same melancholy accusation.

It may be admitted that a hundred years ago there was more ceremonious politeness and a greater stress laid upon conventional forms in social and professional intercourse. But he who reads the history of those days will be convinced that beneath the polished exterior there was far more dislike, envy, and bad feeling than exist to-day.

John Hunter died from a quarrel with his hospital colleagues. In the eighteenth century all medical Europe rang with the quarrels between Cullen and Brown and their respective adherents. In the time of Garth a furious war raged between the supporters and opposers of the dispensary system. That was the age of scribblers, and prominent physicians were constantly being lampooned by their less known enemies.

Says Dr. Wynter to Dr. Cheyne:

> "Eat grass, reduce thyself and die,
> Thy patients then may live."

And some punctilious friend wrote of Sir Richard Blackmore, schoolmaster and physician:

> "In vain his drugs, as well as birch he tried,
> His boys grew blockheads, and his patients died."

Dr. Armstrong, author of the "Art of Health," confessed that he never attained a large practice because "I could not tell a heap of lies in my own praise, nor intrigue with nurses, nor associate, much less assimilate, with the various kinds of pert, insipid, lively, stupid, well-bred, impertinent, good-humored, malicious, obliging, deceitful, drivelling gossips; nor enter into *juntos* with people I did not like."

A great part of the courtly, not to say obsequious, manners of the last-century physician was assumed as a feature in his business.

"If you would be esteemed very wise, sober, and grave," writes Mead to a young physician, "you should then learn most obsequiously to fawn and soothe man, woman, and child, since few else will thrive well."

It would be quite easy to cite many more illustrations in evidence that there is now more mutual good feeling and kindness, and less coarseness and vulgarity among physicians than there ever has been. The tendency to excessive specialism, at the expense of general knowledge and culture, must be admitted, and scientific study does not tend *emollire mores*.

It would be an interesting task to trace this gradual decline of learning, in its broadest sense, among eminent physicians of the past. Of the Elizabethan physicians Lord Bacon says: "For you shall have of them antiquaries, poets, statesmen, humorists, merchants, divines"—everything in fact except skilful practitioners.

Later Sir William Temple paid a similar tribute to the Faculty, which Dr. Johnson still later accepts with some hesitation, "Whether what Temple says be true, that physicians have had more learning than the other faculties I will not stay to inquire; but I believe every man has found in physicians great liberality and dignity of sentiment, very prompt effusion of benevolence, and willingness to exert a lucrative art where there is no hope of lucre."

Of the modern physician it cannot be said that he is a man of wide learning. He seeks rather to accumulate scientific knowledge and technical skill. Whether a reaction toward a more general culture, at least as a basis for his education, might not be a greater help in the practice of his art, is a burning question just now.

THE IMPORTANCE OF HOLIDAY SEASONS FOR PHYSICIANS.

WHEN Addison tells us in the "Spectator" that "the preservation of life should be only a secondary concern, and the direction of it the principal,"[1] he says what is very true, for a well-directed life insures a healthful life. While, therefore, the higher aim is to be approved, and undue

[1] Spectator, No. 25.

solicitude about the health should be condemned, it is understood that when to every man in the performance of his daily duties work becomes irksome and painful, respite is imperatively demanded, he cannot longer persist in his tasks without physical detriment.

It cannot be too much kept in mind that labor is physiological only when it is agreeable, and that every hour spent in goading a tired organism to toil, may have a pathological outcome. When study is attended with that sense of *bien être* which indicates that the brain is abreast of its tasks, then and only then is it profitable; all experience will attest this. When the physician can go through his regular routine of daily calls with interest, even with zest, and a flow of spirits, he is working to advantage; when interest flags and the spirits droop, and there is organic discomfort, it is time for him to have a season of rest; all this is so plain as to need only to be stated.

Now that the holiday season is well-nigh over, and business men are returning to their offices and clergymen to their pulpits, it is well that that model of perseverance and devotion to a good calling, the city physician, who has been sweltering at home during the hot season, should ask himself whether he can afford not to take suitable holiday enjoyments?

The question hardly deserves discussion, for every medical man will be ready to give the proper answer in its application to everybody but himself. He knows that it is a law of nature that physicians, as well as other men, should have periodical seasons of rest, relaxation, and recreation. He is ready to urge upon his patients the importance of their availing themselves of the hygienic benefits of frequent change of scene. He tells the active man of business, the public officer, the banker, the merchant whose liver and whose kidneys are becoming sluggish, whose brain will not work well, to get out of the old ruts, and he orders the dyspeptic clergyman from his pulpit to the prairies, the forest, or ocean. As for himself, however, while others go to the seaside he stays at home; the peculiar nature of his profession forbids that he should absent himself from his office longer than a day or two. The clergyman's salary goes on as usual while he is away, and the manufacturer may direct his business by telegraph or by letter, but the physician sees the perspective of his vacation pleasures marred by a dark background of lost fees and estranged patrons; in short, pecuniarily he cannot afford the recreation he needs. We are speaking, of course, of the great body of struggling practitioners, who have every interest in keeping what practice they have and in adding thereto—not of those fortunate ones who were born with silver spoons in their mouths. There is, moreover, an important distinction to be made in this respect between city and country practitioners. The city physician is subjected to causes of ill-health from which his country *confrère* is comparatively exempt. The latter habitually breathes purer air; has invigorating rides over hill and plain where nature in her grandeur and loveliness breaks in on the monotony of his toil; if he has but a few patients, these scattered over a wide area occupy the larger part of his time, giving him his fees and mileage; he has some gardening, and perhaps some farming, which distract his mind from the cares of his profession, if they do not add much to his income; his taxes are less than those of his city brother, and it costs him in every way less to live. He has fewer eager competitors, and has far less reason for harassing anxiety than his metropolitan friend. If the latter has social and æsthetic and professional advantages of a higher order, and more leisure for study and research, his manner of life is more sedentary and consequently less invigorating, and he labors under the disadvantage of not being able to live easily on a thousand a year; he has a multiplicity of cares and wants that are peculiar to his condition; he feels constantly the pressure of fierce competition, and unless possessed of rare equipoise of temper and a philosophic mind he will be given to worry, and this, whether his practice be considerable, or whether it be little. Statistics have shown that out of equal numbers of city and country practitioners the balance of longevity is in favor of the latter, who seem, as we have indicated, to be especially favored in the benevolent economy of nature. It is apparent then, that regular holiday seasons must be of great hygenic benefit to every hard-worked medical man, and especially to the harassed practitioner of the town, to whom it is, indeed, a physiological necessity.

Some time since we had a brief conversation with a medical gentleman of repute in a neighboring city, who acknowledged that he had not for ten years had a vacation of even one week! The experiment, he affirmed, would have been too perilous! He felt that he must be at his post day and night. He had a large family to support, and he had no practice to lose. He never needed money more, and cessation from work would be ruin! On questioning this individual we ascertained that life was to him a constant worry, and work was pain. Appetite and digestion were failing, and he no longer slept well. He had become "disgusted with his practice and with his patients," and it was with difficulty "that he could treat them with any sympathy and patience." "I hate those old cases, and those old faces," he said, "collecting has become irksome, and the sight of an unpaid bill makes me desperate." Some vehement expostulation on our part, and urging of our friend to break away from his work at whatever risk and cost financially, was certainly of no avail; and we have within a few days seen in a local paper the notice of his death, "from mental alienation and softening of the brain."

We do not doubt that there are many in the profession to-day who are the subjects of experiences similar to those above depicted, and who have the same appeals from the depths of the unconscious life; appeals and warnings which cannot safely be disregarded. It will not do to trifle with these imperious feelings of the organic nature, indicative of discomfort, maladjustment, and uncompensated waste in the highest centres of innervation. The part of true economy, as well as the part of duty, is always to seek suitable relaxation and rest.

THE PROGRESS OF THE COLLECTIVE INVESTIGATION MOVEMENT.

As the result of considerable previous work on the part of Gull, Paget, Clark, Lister, and other English physicians, an International Committee on Collective Investigation was organized at the meeting of the Medical Congress in Copenhagen. This Committee, after two meetings, arranged for the nomination of the following Working

Committee at the close of Sir William Gull's address: For England, Gull, Humphry, and Mahomed; for India, Fayrer; for Denmark, Trier and Lange; for Scandinavia, Bull; for Russia, Rauchfuss; for Switzerland, Despine; for Germany, Ewald and Bernhardt; for Austria, Schnitzler and Pribram; for France, Bouchard and Lépine; for the United States of America, Jacobi and Davies; for South America, Gutierrez Ponce. Professor Koranyi was subsequently added as representative of the kingdom of Hungary.

The above Committee immediately met and organized. Its first work was to appoint an Executive or Sub-Committee, which was done in the following resolutions:

1. That the Secretary be instructed to prepare a statement as to the objects of the Committee, for translation and publication in the journals of the various countries represented.

2. That a Sub-Committee be appointed.

3. That for the present it consist of not more than three members.

4. That the three members be Professor Humphry, Dr. Mahomed, and Dr. Isambard Owen.

5. That the Sub-Committee be directed in the first instance to prepare a list of subjects suitable for investigation by the Committee, and to submit the list to the members of the Committee for choice; further, upon such choice being made, to prepare memoranda and questions upon the subjects chosen, and submit them to the members of the Committee in like manner; and that, upon the acceptance of the memoranda and questions by the members of the Committee, the representatives of each nation be left to obtain the information required, independently, in such manner as they may prefer.

6. That each member of the Committee be requested, on returning home, to write his views on the subject of the proposed investigation to the Sub-Committee, who will communicate again with the members.

Thus the work stands for the present.

It is getting to be more and more felt by the medical world that collective investigation is to be a powerful agent in medical progress. But it is still more surely seen that it is an agent which has to be managed very carefully. There are only certain lines of medical inquiry along which it will as yet serve any good purpose. And eventually it will be found that to get trustworthy results collective investigation must be confined to professional men of known character and capacity, in other words, collective investigation must be limited to experts.

FURTHER CONTRIBUTIONS TO THE CHOLERA GERM QUESTION.

Dr. H. Van Dyke Carter, of Bombay, in *The Lancet* for September 6th, describes the results of his investigations of cholera stools. He has discovered an organism which he figures, and which certainly resembles very much the comma-bacillus of Koch. As Dr. Carter represents it, however, it is longer and has more of the spiral curves, being unmistakably, if the drawings are correct, a spirillum. This organism was not found in every case of cholera examined, while it was found, though rarely, in the stools in dysenteric and diarrhœal cases. Its real character was not tested by cultivation, however, so that Dr. Carter's observations have in themselves but little value.

From Marseilles come reports of a different nature regarding the cholera organism. Drs. S. Maurin and Lange, who have been working in that city since the departure of Koch, announce that they have found a *mucor* which they believe to be the actual agent in the propagation of cholera. This mucor is really only the mature form of the comma-bacillus, out of which it develops.

It appears, according to an account given in the *British Medical Journal*, on the fourth or fifth day, on the putrefying stools of cholera, and on these only. It has the form of a mycelium, the tapering ends of which are surmounted by cup-shaped sporangia, which burst on the slightest agitation, discharging vast numbers of spores. These spores require, for their germination, to be deposited on, or to come into contact with, some putrid organic matter, when they develop into a mucor of another form, an anaërobium, which they believe to be the immediate cause of the phenomena of the disease, and which again, in its turn sporifying, gives birth to the bacilli of Koch.

The bacilli in themselves are innocuous, but, deposited on a putrid medium, and in contact with the air, they develop the first-mentioned mucor, and the cycle is renewed.

The first mucor, unlike the bacillus, possesses in a high degree the power of resisting the action of so-called disinfectants; it is not killed by ten-per-cent. solutions of nitric or of hydrochloric acid; it vegetates freely in a solution of carbolic acid in like proportions, and can sustain any temperature up to 150° Cent. (302° Fahr.), but above this it breaks up, as it does also in a ten-per-cent. solution of tincture of iodine; and a specimen mounted in oil of turpentine went through its whole development up to the discharge of its spores.

The *British Medical Journal* is inclined to give some credence to the above-described account. It appears to us, however, to be beyond the bounds of probability that the cholera bacillus should have any such life-history as the Marseilles investigators assert. Dr. Koch cultivated it in gelatine, in broths, and on potato, yet never found any such mucor as MM. Maurin and Lange describe.

EXAMINATION FOR ALBUMINOSE OR PEPTONE IN THE URINE.

In 1872 Tanret proposed, as a reagent for the quantitative determination of the albumen, the acetic solution of the iodide of mercury and potash, of which the formula is iodide of potassium, 3.32 grms.; bichloride of mercury, 1.35 grm.; acetic acid, 20 c.c.; and distilled water, 64 c.c. As an agent for the precipitation of albumen, says Mehn, this reagent is valuable; it does not precipitate urea or mineral salts; it is very sensitive and much superior to nitric acid, needs no heat and keeps well.

Three years ago Mehn discovered that this solution precipitates the proteid material known as albuminose or peptone. In examining a very limpid acid urine, shaken until quite frothy, he has found that after separating the albumen coagulable by heat, a certain degree

of agitation still caused considerable frothiness. The urine contained neither pus, sugar, nor blood, yet the solution caused, in this urine deprived of albumen, an abundant precipitate, which water acidulated with acetic acid and alcohol did not dissolve. Furthermore, he has several times examined urines which contained no albumen, but only albuminose or peptone coagulable by this reagent, and also a mixture of coagulable and non-coagulable albumen. In some specimens of urine he has found coagulable albumen; this being removed the urine was still feebly clouded by nitric acid. This second cloud being removed, he obtained an abundant precipitate, due to peptone, by the acetic solution of the iodide of mercury and potassium.

Various attempts have been made to extract the whole of the coagulable or non-coagulable albuminous material with five volumes of alcohol, after acidulating with acetic acid, and also to obtain the albuminose of a liquid deprived by heat and filtration of coagulable albumen. It has been found that the results are of no value, since the peptone is not altogether insoluble in the alcohol. The addition of ether to the filtrate still gives an albuminous precipitate. Nor have any very satisfactory results been obtained by employing neutral solvents, such as absolute alcohol and sulphide of carbon. The solution under consideration seems to give the best results. Specimens of urine containing peptone seem to be rare, although some observers seem to think that the cloudiness caused by the mercury reagent in boiled urine is entirely due to that body.

At present we do not possess any means of isolating albuminose or peptone, other than those which combine with the materials from which it seems impossible to separate it without altering it; and the rules which apply to ordinary or artificial peptones do not apply to urine peptones, and cannot until the identity of the two has been demonstrated, which has not as yet been done. While it is theoretically admitted that all albuminous materials subjected to the action of pepsin, at a sufficiently elevated temperature, finally gave a peptone whose centesimal composition is constant, it is not the less true that under the name peptones are embraced products distinguished by their different reactions with the same reagents. Peptones obtained by the action of pepsin are precipitated by the iodide of mercury and potassium solution, whilst those obtained by the action of pancreatine are not.

This solution is also quite sensitive to the presence of semen in urine, giving a precipitate which is more or less abundant. While, therefore, a valuable reagent for the detection of peptone, it should be used with great care, as errors may result from the formation of other precipitates.

PUERPERAL EPILEPSY.

The older writers, says M. Ch. Féré, believed eclampsia, whether infantile or puerperal, to be a neurosis analogous to epilepsy or hysteria. But since it has been discovered that in scarlatina and pregnancy there is often albuminuria, it has been the custom to explain all cases of eclampsia in these conditions by the action of the poisoned blood upon the nerve-centres. M. Féré has brought forward in the *Archives de Neurologie* of July, 1884, some observations and reasons in support of the view that puerperal eclampsia, for example, is the expression of a neuropathic state in which the conditions in pregnancy are only the exciting cause. Puerperal eclampsia, he thinks, may be regarded as an acute epilepsy or an "eclamptic epilepsy."

If the antecedents be carefully inquired into, in cases of puerperal eclampsia, there will generally be found, says Féré, a hereditary or acquired neuropathic history. A number of cases are cited also in which the puerperal eclampsia, so-called, was only the beginning of a chronic idiopathic epilepsy.

The influence of pregnancy upon the course of epilepsy has been investigated by several observers with somewhat contradictory results. On the whole, however, it appears that during pregnancy the number of epileptic attacks is diminished. It is also well known that epileptics, and "neuropathics" generally, often pass through pregnancy and even scarlatina without any convulsion. In explanation of these facts, however, Féré puts forward the view that in those disposed to epileptic attacks there exist various epileptogenic zones, *e.g.*, gastric, uterine, peripheral, etc. In some cases the irritation must be gastric or peripheric, in other cases uterine, in order to excite the paroxysm and call forth the disease. It is known that in puerperal eclampsia, albuminuria does not always exist. Thus Charpentier alone cites one hundred and forty-one cases of this kind ("Traité pratique des accouchements," 1883). And Nothnagel admits that puerperal eclampsia is sometimes the result of an irritation of the uterine or sacral nerves acting upon an unstable nervous system.

Finally, many persons suffer from albuminuria and some degree of uræmia without having convulsions.

M. Féré has made out a case, therefore, which deserves some attention. Physicians should not be too ready to ascribe puerperal eclampsia entirely to blood-poisoning. They ought to be especially watchful when patients who are pregnant have a well-marked neuropathic history. At the same time, practical experience shows that the large majority of nervous and hysterical women go through pregnancy safely, showing that the pregnant uterus does not often become an epileptogenic zone.

INFANT FEEDING.

Upon nothing does there seem just now to be more disagreement than the subject of infant diet. The points in dispute are: the mode of diluting cows' milk and the best diluent; the use of mixed milk or of the milk from a single cow; the value of condensed milk; the value of infant foods; the question of a wet-nurse or artificial feeding. These points are by no means satisfactorily settled. One evidence of this is seen in the letters which appear in the present issue of The Record. We observe, also, in a current issue of *The Lancet and Clinic*, a carefully written article by Dr. C. W. Earle, in which he says, among other things, that "condensed milk seems to agree with a considerable number of children, but in many cases a sufficient quantity is not given to nourish a child. Used in sufficient quantities, and diluted with rice- or barley-water, it is without doubt one of the best of artificial foods." On the other hand, the

editor of *The Kansas City Medical Record*, in an excellent article upon the subject of infant diet, states that condensed milk has always proved hurtful in his hands. Some contributions from our readers to this subject of infant feeding would be timely. Writers should, however, be careful not to go over old ground more than possible.

PATIENTS FROM THE COUNTRY OBTAINING ADVICE FREE IN THE CITY.

THE thrice-told tale, yet always of painful interest to the struggling rural practitioner, concerning the abuse of medical charity, comes to us from Connecticut in a communication from Dr. Donaldson to the Medical Society of the County of New York. We are glad to refer to the practice, that we may condemn it.

It appears useless to say that rich patients from the country have no right to gratuitous services. They come, nevertheless, and the college clinics and hospital wards welcome them with an eager cordiality not to be mistaken. It is safe to say that it is impossible to find out the pecuniary liability of every stranger, but, with a little care on the part of clinical lecturers and hospital men, the evil can be very much lessened. It is perfectly competent for such gentlemen to refuse to prescribe for any but the really needy; but, we regret to say, the thirst for clinical material overcomes many other considerations, and we oftentimes find ourselves preaching in vain, and are as far from a remedy as ever.

News of the Week.

THE MANAGEMENT OF THE NEW YORK POLYCLINIC, have during the past summer made some improvements which have added greatly to the capacity of the school and the comfort of the physicians who study there. The library, waiting- and reading-rooms have been enlarged and newly and neatly furnished. The clinic-room for diseases of the throat, nose, eye, and ear has been made twice the former size, and has now thirty-one stalls and Mackenzie condensers, which as many students can employ at once. On the second floor are three large, well-lighted and ventilated lecture- and clinic-rooms, capable of seating in all three hundred persons, a laboratory with twenty stands, two waiting-rooms for patients, and a private examining-room. The school has been furnished with stationary and portable batteries, electric bells and clocks, which are sounded at the hours. In one amphitheatre the clinics in gynecology, surgery, and skin diseases are held. The second lecture-room is devoted to clinics in diseases of children, diseases of the mind and nervous system, and orthopedic surgery. A third room is used for diseases of the chest, physical diagnosis, general medicine, and practice in surgical dressings, bandaging, etc. During last session, as shown by the catalogue, one hundred and eighty-two practitioners studied at the Polyclinic. The purchase of the large property heretofore in part occupied by the Polyclinic, means that the management believe in the future of this institution. During the coming year the following clinics will be given weekly: gynecology, surgery, diseases of children, diseases of the skin, diseases of the mind and nervous system, eye, throat, nose, and ear, clinical chemistry, obstetrics, chest, diagnosis, and medicine.

MR. LAWSON TAIT, who has been on a brief visit to this country, sailed for his home on Saturday last. On the Friday evening preceding he and Mrs. Tait were entertained at a dinner given in their honor by Dr. and Mrs. Fordyce Barker. Among the other guests present were Dr. and Mrs. T. A. Emmet, Drs. T. G. Thomas, Isaac E. Taylor, W. T. Lusk, W. M. Polk, A. A. Smith, and George F. Shrady. It is needless to say that the occasion was an enjoyable one to all concerned.

RAMSEY COUNTY MEDICAL SOCIETY AND THE DEATH OF DR. STEWART.—At a special meeting of the Ramsey County (Minnesota) Medical Society, held at Dr. Stone's office, the following resolutions were unanimously adopted:

Whereas, In the sad and sudden death of Dr. J. H. Stewart this Society recognizes its loss of an esteemed and respected member;

Resolved, That we, his former associates, desire to record our sorrow and testify our warm appreciation of his professional and manly qualities. He was learned and more than ordinarily skilful in the practice of his profession, endearing his patients to himself by a most happy faculty. By his death we have lost a professional associate, conscientious and considerate, whose wise and superior counsel we shall deeply miss.

Resolved, That we deplore the loss to the community of which he was so eminent and respected a member, and whose trusts so frequently confided to him were so conscientiously and honorably guarded.

Resolved, That we tender to his greatly bereaved family our deepest sympathy.

Resolved, That a copy of these resolutions be forwarded to the family, and that they be printed in the daily papers, the *Northwestern Lancet*, and the New York MEDICAL RECORD.

AN OFFICE FRAUD AND CONFIDENCE MAN ABROAD.—A young, short, thick-set mulatto (a graduate of the College of Physicians and Surgeons, New York) is going about town obtaining money from physicians and others on one of many pretexts which appeal to one's sympathy. Numbers have been victimized by the scamp. We learn that the fellow has been carrying on this peculiar business for some years, and that he has served a term in Sing Sing Prison for forging the name of the Rev. Dr. Deems, of this city, on a check.

A COMPLIMENTARY DINNER was tendered to Dr. J. V. Shoemaker, of Philadelphia, by his friends, on his return from Europe, at the St. George Hotel, on Saturday evening, September 20, 1884.

AMERICAN GYNECOLOGICAL SOCIETY.—The Ninth Annual Meeting of this Society will be held at the Palmer House, Chicago, Tuesday, Wednesday, and Thursday, September 30 and October 1 and 2, 1884.

ASSISTANT PHYSICIANS WANTED IN THE HUDSON RIVER STATE HOSPITAL.—To fill a vacancy in the office of First Assistant Physician at the Hudson River State Hospital, and for the appointment of a Third Assistant Physician and Sanitarian at the said hospital, open competitive examinations of applicants for the ap-

pointments will be held under the rules of the New York Civil Service Commission. Candidates for the positions will be examined in general medicine and surgery; in psychiatric medicine; in the anatomy, physiology, and pathology of the brain and nervous system; in the use of the microscope and instruments of precision; in sanitary science and hygiene; in foreign languages; and also in regard to special qualifications for the respective appointments.

It is required that candidates be graduates of a reputable medical college, and have completed the term of service required by a regular appointment in the resident medical staff of a general hospital, and that they be familiar with the practice of home and foreign institutions for the insane.

There are no restrictions imposed as to the residence or citizenship of candidates.

The examinations will be held at such times and places as the Civil Service Commission may designate. Ten days' notice of each examination will be mailed to all eligible applicants of record, and will be published in the State paper, and in one other journal published in Albany.

Applicants will be admitted to examination upon the production of the official notification to appear for that purpose.

The First Assistant Physician will receive $3,000 salary per annum and his board; the Third Assistant Physician will receive $1,000 salary per annum and his board.

Printed application papers for admission to the competitive examinations will be mailed to candidates on application to Dr. Joseph M. Cleaveland, Superintendent Hudson River State Hospital, Poughkeepsie, Dutchess County, N. Y. Applications must be forwarded on or before October 1, 1884.

Mississippi Medical Society.—The Tenth Annual Meeting of the Mississippi Valley Medical Society ("The Tri-State Medical Society") will be held at Springfield, Ill., September 23–26, 1884.

American Public Health Association.—The opening session of the Twelfth Annual Meeting of the American Public Health Association will be held on Tuesday, October 14th, in the main hall of the Liederkranz Building, St. Louis.

The National Conference of the State Boards of Health, postponed from August 7th, at Washington, will also be held here during the same week.

Open to Universal Competition.—The Cartwright prize of the Alumni Association of the College of Physicians and Surgeons of New York is open to the competition of the alumni of *any* medical college.

It consists of a prize of $500, to be awarded to the best medical essay submitted upon any subject the writer may select. The award will be paid as soon as the successful article shall have appeared in print.

If no one of the competing essays be deemed sufficiently meritorious the prize will not be awarded. An essay in order to be held worthy of the prize must contain results of original investigation made by the writer. An award of this prize will be made at the commencement of 1885. Essays must be sent to a member of the Prize Committee before April 1, 1885. Competing essays must each be marked with a device or motto and accompanied by a sealed envelope similarly marked containing the name and address of the author.

R. W. Amidon, M.D., 18 W. Twenty-first Street, Chairman; Robert Abbe, M.D., 32 E. Twenty-fifth Street; Walter Mendelson, M.D., 209 W. Forty-sixth Street, Committee on Prize Essay.

Victor Hugo and the Ambulance Service.—The establishment of an ambulance service like that in New York is very nearly an accomplished fact in Paris. Dr. Henri Nachtel has published a pamphlet upon the subject. It is prefaced by the following characteristic letter from Victor Hugo:

31 Juillet, 1884.

New York has begun, Paris will continue. That which you advise, Monsieur, is sustained by reason and by evidence. Success will confirm your confidence. The plan is clear, it is appropriate, it is humane. I commend you and I congratulate you. Victor Hugo.

The Singular Persistence with which the *Midland Medical Miscellany* continues to appropriate editorials and other matter from The Medical Record without acknowledgment interests us very much. It is furnishing us an exciting psycho-journalistic study. It is, we think, an exquisite case of moral *Schwächezustand*, or perhaps of imperative conceptions (combined with prehensions), there being in its midland mind no solution in the general continuity of the *meum* and *tuum*.

An Anthropological Congress was held recently in Breslau. Among the interesting contributions made at that time was one by Professor Schaffhausen, of Bonn, who has found, as the result of a series of cranial measurements, that the antero-posterior or longitudinal growth of the skull ceases before the lateral growth, and that the longitudinal growth bears a distinct relation to that of the body, while the lateral growth stands in relation to the intelligence. Here is then a physical basis for the schoolmaster to work upon in assigning his tasks and making his prophecies.

Prizes for Essays on the Prevention of Blindness.—At the Hygienic Congress held at the Hague, August 27th, a prize of 2,000 francs was awarded to Dr. Fuchs, of Lüttich, for an essay on the "Causes and Prevention of Blindness." The prize of 1,000 francs offered for an essay on a similar subject was awarded to a German author, whose name, strange to say, could not be discovered.

Works of the Late Dr. Farr.—A movement is on foot to collect and publish the statistical papers of the late Dr. Farr. The editor will be Mr. Noel Humphreys.

The Hygienic Congress at the Hague has unanimously adopted the propositions of Professor Proust expressing the desirability of the meeting of a new International Sanitary Conference and the creation of a permanent international scientific committee to act against epidemics. It has also passed a resolution in favor of an international sanitary code. Holland will be asked to be the interpreter of the views of the Congress to the other Governments. In the Second Section, on the 27th ult., a long debate took place upon cremation. In the general meeting of the Congress, Mr. Corfield, of London, defended the axiom that science is the enemy of

disease. M. Trelat, of Paris, spoke upon the temperature which should be maintained in dwelling-houses. Mrs. Bovell-Sturge, of London, condemned the system by which at present the State provides for the education of children who have been abandoned by their parents, and advocated their being educated in private houses.

A New Hospital at Rome.—The Pope has given $200,000 for the erection of a new hospital at Rome near the Vatican.

More Yellow-Fever Cases in New York and Brooklyn.—Two sailors died of yellow fever at the Long Island College Hospital last week. They came from the West Indies on the British steamer African, and landed at Perth Amboy, N. J.

A steerage passenger on the Newport, from Havana, which arrived at this port recently, was found at a hotel on West Fourteenth Street apparently suffering from yellow fever. He was at once put in quarantine.

At this time of year there is no possible danger of yellow fever extending through the city.

The Sanitary Council of Maryland held a successful meeting at the Blue Mountain House, September 17th, 18th, and 19th. Among the subjects discussed were: "The Adulterations of Food and Medicines;" "The Pollution of the Water-courses in Maryland;" "The Relation of the Diseases of Animals to the Human Race;" "The Sanitary Problems of the Cities and Towns of Maryland;" "The Relation of the Press to Sanitary Work;" "The Relation of Teachers to Sanitary Work;" "The Physical Dangers of Alcoholic Beverages;" "The Relation of the Clergy to Sanitary Work;" "The Duty of State and Municipal Governments in Connection with the Public Health;" "The Disposal of the Dead."

A Reception to Dr. Playfair, of London, was tendered by Dr. T. Addis Emmet at his residence in this city, on September 26th.

Medicine at Winnipeg, Manitoba.—A correspondent of the *Canadian Practitioner* writes: "Manitoba has been making the same rapid strides in medical matters as in all other departments. With the rapid influx of people came an equally rapid increase of doctors, until we can boast of the largest proportion of medical men to the total population of any province in the Dominion. Indeed, at present, the field is too well occupied, especially in our cities and towns. Without doubt, however, there are many points in rural districts where a doctor's presence would be hailed with pleasure, and where he could make a present living and be reasonably sure of a future reward commensurate with the arduous nature of his early work." Winnipeg having got a medical school started, is soon to have a hospital.

Doctors in Canada and the United States.—There are, says Dr. Sullivan, three thousand five hundred and seven physicians in Canada, or one to about fifteen hundred inhabitants. Indiana with about the same population as Ontario, has three thousand two hundred and seventy-five more doctors. Canada has about nine hundred medical students distributed among eight medical schools.

The Philadelphia Maternity Hospital.—The obstetrical staff of this hospital has filed a petition with the managers asking for the appointment of a female resident physician.

The Mosquito as a Yellow Fever Vaccinator.—The editor of the *St. Louis Courier of Medicine* gives an account of the studies of Dr. Carlos Finlay (*Cronica Medico quirurgica de la Habana*), with reference to mosquitoes and yellow fever. Dr. Finlay believes that he has demonstrated that yellow fever is inoculable by the sting of the Cuban day-mosquito during the third, fourth, fifth and sixth days of its evolution, but not during the first two days nor after the sixth, no matter what be the severity of the symptoms at those periods. The duration of incubation offers the same variations in the inoculated as in the natural disease, in either case varying from five to twenty-four days. The duration and intensity of the fever produced by inoculation by the mosquito appears to be in proportion to the number of punctures and the quantity of inoculable matter retained by the insect's sting. The inoculation by one or two punctures in no case produced any other morbid phenomena than those of benign natural yellow fever. Dr. Finlay thinks that the results already obtained warrant the assertion that the inoculation of yellow fever by one or two mosquito bites is a plausible means of imparting, without peril, immunity against the severe forms of the disease to which those are exposed who dwell in an infected district.

Through Quarantine.—Our India medical exchanges smell so strongly of smoke and carbolic acid as to give a realistic sensation of the existence of an epidemic.

A School of Dentistry is to be opened at the beginning of the winter term at the University of Leipzig, under the direction of Professor Dr. Fr. Hesse.

The Medical Department of the Prussian War Ministry, assisted by the Medical Department of the Bavarian and Wurtemberg War Ministries, and the Saxon Sanitary Board, are now bringing out a sanitary report of the German armies in the Franco-German war of 1870–71. The first and fourth volumes have just appeared.

Mr. Tait's Tribute to the Medical Colleges.—Mr. Lawson Tait has heralded his entrance to this country by some very flattering remarks. He wishes now that he had come to America instead of Germany to finish his medical education; and he prophesies that "ere long it will be to the medical schools of America rather than of Europe that English students will travel" before settling in practice. This is very complimentary, and it has already been appropriated by some of our contemporaries as a truthful tribute to the medical colleges of the United States, although Mr. Tait had not left the Dominion when he made the remark. Let us not be too easily caught by a somewhat overloaded compliment.

Dermatology in Paris and Vienna.—For a long time it has been noticeable that whoever writes letters from medical Vienna is sure to say a great deal about the dermatological teaching. Vienna has certainly won pre-eminence through the world in this department of medi-

cine. In a recent issue of *Le Progrès Medical* the editor devotes a long article to the subject of the decadence of dermatology in Paris, and its flourishing condition in Vienna. In Paris dermatology is at a low ebb because the clinics are not well organized and the material at disposal not utilized. There seems to be a good deal of official dulness and obstruction at the bottom of it all. In Vienna the clinics are well organized, the material is centralized, and all can be made use of. Perhaps the large excess of ignorance, filth, and syphilis has something to do with the brilliancy of the skin clinics. Vienna, though a great medical centre, has one of the highest mortality rates in Europe. *Le Progrès Medical* advises the reorganization of the Hôpital St. Louis, which contains a wealth of dermatological material.

Instruction in the Methods of Examining Micro-organisms.—It is well known that the ordinary examination of fluids and tissues for micro-organisms does not involve, generally, any very delicate or complex procedures. No doubt in time a practical acquaintance with these details will be thought as necessary to the student as dissection. Educational institutions already see the need of teaching "bacteriology." Recently the Berlin Government has taken a new step. Herr von Gossler, Minister of Public Worship, Education, and Medical Affairs, has ordered that a certain number of medical men are to be summoned to Berlin every year, to go through a course of study, lasting from a fortnight to three weeks, in order to learn the new methods of investigation connected with bacteria and micro-organisms, but chiefly to become acquainted with everything connected with the comma-bacillus and the methods of cultivating it according to Koch's method. The several Federal Governments have been already requested to select a number of medical men for this course, and to inform them to hold themselves in readiness to come to Berlin. The day for the commencement of the first course, says the *British Medical Journal*, has not yet been fixed, but will be very shortly.

The Cholera.—The epidemic continues to decline. The number of cases reported in Italy, September 17th, was 581; a week later the number was 435. During the same time the daily number of new cases in Naples has fallen from 463 to 251. The total number of deaths from cholera in Italy up to September 24th was 7,212. This represents fully twice that number of cases. The mortality in the past weeks, if correctly given, has averaged over fifty per cent., showing that the disease is very malignant or treatment is very ineffectual. It is probable, however, that the number of cases reported is much below the truth.

In the south of France the cholera continues to attack small towns, but with no great severity. There have as yet been only about 300 cases in Spain, and these chiefly in the Eastern Pyrenees.

Suicide of a Medical Student.—Mr. John F. Keating, a medical student in the Medical Department of New York University, committed suicide last week by shooting himself with a pistol. The cause given by him was the sickness and approaching death of his mother. It seems probable that he was not sane at the time.

THE SIMS MEMORIAL FUND.

To the Medical Profession and Others throughout the World:

The great achievements of Dr. J. Marion Sims call for some more lasting testimonial than obituaries and eulogies. To him medical science is indebted for much brilliant and original work, especially in gynecological surgery. Those who have been benefited by his teachings and new operations, and such as have had the direct advantage of his personal skill are among the first to recognize and acknowledge this debt.

To him is due the honor of giving the first strong impulse to the study of gynecological surgery in America.

It is believed that the medical profession everywhere, the vast number of women who owe their relief from suffering directly to him, and those who realize the benefits he first made possible, will gladly unite thus to honor the man through whose original and inventive genius such blessings have been conferred upon humanity.

At the suggestion of many friends, therefore, the subjoined committee has been organized, and it is proposed that a suitable monument be erected to his memory in the city of New York.

To this end the active co-operation of the medical profession and the many other friends of Dr. Sims throughout the world is respectfully solicited. Contributions of one dollar and upward may be forwarded to the journal which has been constituted the treasury of this fund—The Medical Record, New York.

Reviews and Notices.

Osteotomy and Osteoclasis for Deformities of the Lower Extremities. By Charles T. Poore, Surgeon to St. Mary's Free Hospital for Children, New York. 8vo, pp. 187. New York: D. Appleton & Co. 1884.

Dr. Poore, who has already become so well known by journal articles on bone surgery, has condensed his experience in the work before us. He has succeeded in doing this in a very satisfactory way. He has gone over the subject in a very thorough manner, thus giving a concise treatise on osteotomy. This has been very much needed, considering the rapid progress which has been made in this department of surgery within the last few years, and the number of articles of rare value which have been scattered through the journals Dr. Poore has not only described in a very intelligent and concise manner all the different methods of osteotomy advocated by the leading surgeons abroad, but has studied the same from the light of a personal experience which has been sufficiently large for purposes of deduction and analysis. He is not backward in stating his preferences regarding procedures, but he does so with becoming respect for the opinions of others, and with a modest candor which is quite convincing. There is manifested throughout a disposition to give the facts to the reader with such conclusions as can be legitimately drawn from them.

Dr. Poore speaks strongly in favor of the chisel as against the saw, for the performance of osteotomy. The obvious reason for this is that he has never used any variety of saw, and is particularly skilful with a chisel of his own device, which, by the way, is a perfect instrument of its kind. It is a matter of personal preference for the chisel, which he has, under the circumstances, a perfect right to maintain. It is needless to follow the author through the various stages of his work; suffice it to say, however, that he puts his points fairly, and draws his conclusions logically as to methods of treatment recommended. His advocacy of MacEwen's supra-condyloid operation is what might be expected, and is in full accord with the verdict of the surgical section of the late meeting of the International Medical Congress. We cannot too strongly commend the clear and succinct manner in which the author weighs the indications for treatment in particular cases. In so doing he shows a knowledge of his subject which is as extensive as it is profound, and no one at all interested in orthopedy can read his conclusions without profit. His own cases, which are carefully reported, are valuable additions to the literature of the subject. These, together with others, which are only summarized, contain so much practical information and sound surgery that they give a special value to the work, altogether independent of its other excellences. It is a good book in every way, and we congratulate the author accordingly.

Atlas of Female Pelvic Anatomy. By D. Berry Hart, M.D., Lecturer on Midwifery and Diseases of Women, School of Medicine, Edinburgh, etc. With Preface by Alexander J. C. Skene, M.D., Professor Medical and Surgical Diseases of Women, Long Island College Hospital, Brooklyn, N. Y. 4to, pp. 89. New York: D. Appleton & Co. 1884.

"In this Atlas," says the author in his preface, "I have tried to give a faithful account of the anatomy of the female pelvic organs." How he has succeeded can only be appreciated by a careful study of the numerous magnificently executed and accurately delineated plates to be found in this superbly printed volume. It is hardly possible to give any idea of their excellence by any description. They are simply magnificent, and so completely meet every desideratum of the anatomist and practical surgeon that nothing is left to be desired. Very many of the drawings are original in design and novel in execution, illustrating in outline and detail many points in relative anatomy not generally referred to by leading authorities, and in every particular, so far as we know to the contrary, bringing our knowledge up to the level of the latest investigations of the anatomy of the parts, descriptive and topographical. Take, for instance, the study of the female perineum, the reflections of the pelvic fascia and natural relations of the healthy uterus. Many of the plates are beautifully colored, with the principal organs indicated by abbreviated names upon them, after the manner of Gray. This lettering does not in any way interfere with the strikingly artistic effect of the plates as a whole, while they greatly aid, as will be obvious to every student, the proper study of relations of different parts to each other without constant reference to the text. The outline drawings are also models of their kind and do not aim at giving too much in one figure. One point is illustrated at a time, and the collection makes a consistent whole with the more elaborately and accurately detailed chromo-lithographic illustrations. The micro-photographic representations of tissue formation are well executed, but are rather disappointing in their small number, and in some instances sharpness of detail. This is, however, only speaking comparatively in regard to the other plates throughout the work.

The descriptive text is not voluminous. This would hardly be considered necessary in a work of this kind, the main objects of which are to teach by the pencil rather than by the pen. In the higher walks of anatomy, where this remarkable atlas finds a leading place, there is no need for much detail description. The student is expected to have mastered the elements and to have gone on. Hence, evidently following out this idea, the author contents himself mostly with straightforward demonstrations, giving only such word descriptions as shall enable him to make his subject sufficiently understood in consistent outline.

As a new work by a well-known author there is a natural prejudice in its favor, but this becomes the more deeply rooted as we constantly get new views of old fields, new landmarks for better outlooks, new light upon heretofore obscure points. To particularize would be to review all the recent advances made by leading anatomists in the study of female pelvic anatomy—a detail which would be for the purpose of this notice plainly unnecessary. In a word, we can, after the most critical study of its contents, say with the distinguished editor, Professor Skene, that "it is far in advance of any work of its kind yet produced." As such it becomes a necessity for the progressive gynecologist, for the operating surgeon, and for the leading general practitioner. We congratulate the publishers on the reproduction of this grand work and bespeak for it a becoming appreciation by the profession of this country.

Lessons in Longevity: Paragraphs on Home Hygiene and the Art of Prolonging Life. By John B. Hamilton, M.D. Washington: William H. Morrison. 1884.

This modest little pamphlet contains much sound sense as well as sanitary wisdom. The author possesses a graceful style and knows how to adorn his texts, mingling *dulce et utile*.

Origin of Eating Goose on Michaelmas Day.—Queen Elizabeth on her way to Tilbury Fort on September 29, 1589, dined on roast goose and Burgundy wine. She fed so heartily that she required an extra half pint of Burgundy, with which she drank "Destruction to the Spanish Armada." She had scarcely set her glass down when news came of the destruction of the Spanish fleet by a storm. She immediately took another bumper to digest the good news as well as the goose, and ordered that roast goose should be served up to her every year on that day. The court followed the custom, and the people generally soon adopted it. Burgundy wine could be taken at all times.

International Medical Congress.

EIGHTH SESSION.

Held at Copenhagen, Denmark, August 10–16, 1884.

REPORTS OF SECTIONS.

SECTION ON DISEASES OF CHILDREN.

MONDAY, AUGUST 11TH—FIRST DAY.

THE Section was called to order by the President, PROFESSOR HIRSCHSPRUNG, of Copenhagen, who welcomed the members, outlined briefly the work that was to be done, and expressed the hope that the science of pediatrics would receive a new impetus from the labors of the eminent men who had given their adherence to this important section.

He then announced the election of the following officers:

PRESIDENTS.

Professors A. Jacobi, of New York, and Rauchfuss, of St. Petersburg.

SECRETARIES.

Drs. Israel and Wichmann, both of Copenhagen.

The Chair was then taken by DR. JACOBI.

DR. RAUCHFUSS read a paper on

THE EDUCATIONAL VALUE OF POLICLINICS

for the treatment of dieases of children. He maintained that not the least of the benefits that resulted from policlinics was the diffusion throughout the community, and especially among the poor and the ignorant, of a knowledge of hygiene. If ignorant mothers could only be impressed with the importance of observing at least the elementary rules of hygiene, a vast amount of good would be accomplished. Prevention was better than cure.

DR. A. BAGINSKY, of Berlin, then read a communication entitled

THE PATHOLOGY AND TREATMENT OF CHOLERA INFANTUM.

This disease, the author said, is to be reckoned, in Berlin at least, as the chief cause of death in infants. The number of cases of the disease in any given summer is in direct proportion to the height of the temperature of the air, but seems to be only indirectly dependent upon the height of the temperature of the ground, the lowering of the level of the ground water, or the degree of moisture of the atmosphere. The quality of the nourishment and the degree of care which the child receives, as well as the situation of the dwelling, are very important factors in the etiology. Teething has no direct influence on the disease.

As regards pathology, the different forms of summer diarrhœa of infants may be divided into: 1, primary dyspeptic catarrh; 2, genuine cholera infantum (cholera nostras); 2, follicular disease of the intestinal tract; 4, secondary dyspeptic catarrh; and 5, intestinal atrophy. All these processes are as links in a chain, and may pass one into the other. Post-mortem examinations prove the correctness of this statement. Microorganisms are found in the walls of the intestines, and are perhaps not unconcerned in the causation of the disease. The therapeutic management varies according to the form of the disease with which we have to deal.

PROFESSOR HIRSCHSPRUNG, of Copenhagen, then read a paper summing up the results of

OBSERVATIONS ON HÆMOGLOBINURIA

during the first year of life, and gave a demonstration of this condition.

DR. H. REHN, of Frankfort-on-the-Main, followed with a paper on

SO-CALLED ACUTE RICKETS,

in which he attempted to answer the question whether the experiences of later years have enabled us to determine the position of the affection known as acute rachitis.

Most of the papers elicited more or less discussion from those present.

No session was held on Tuesday, August 12th, but the members of the Section, together with those of the Section on Hygiene and State Medicine, made an excursion to the

ASYLUM FOR YOUNG GIRLS

at the Château Jaegerspris near Copenhagen.

On Wednesday, August 13th, no meetings of Sections were held, as all the members of the Congress joined in the excursions to Elsinore and other places.

THURSDAY, AUGUST 14TH—FOURTH DAY.

In the morning the Section held a joint meeting with that on Hygiene and State Medicine.

DR. SCHEPELERN, of Refsnaes, read a paper on

THE TREATMENT OF CHRONIC DISEASES OF CHILDREN AT SEA-COAST HOSPITALS.

The speaker advanced the proposition that sea-side sanitaria ought to be kept open the entire year, winter as well as summer. He then spoke of the good results following a winter course of treatment, dwelling more especially upon the value of hydrotherapy in this connection. Among the diseases of childhood in which great benefit may be derived by a course of treatment at sea-side sanitaria, the author spoke more particularly of the scrofulous affections. One point upon which he dwelt at some length was the value of an increase in weight as evidence of the favorable progress toward recovery in scrofula.

DR. ENGELSTED, of Copenhagen, read a second paper on the same subject. His views did not differ substantially from those of the preceding speaker.

At the afternoon session DR. RAUCHFUSS, of St. Petersburg, read a paper on

CROUP,

in which he argued the question as to how far this condition can be considered, from a clinical point of view, as a well-defined morbid entity.

A discussion followed, which was participated in by PROFESSOR VIRCHOW, of Berlin, and others.

FRIDAY, AUGUST 15TH—FIFTH DAY.

PROFESSOR RAUCHFUSS, of St. Petersburg, occupied the chair.

DR. RUPPRECHT, of Dresden, read a paper on the

ANTISEPTIC TREATMENT OF WOUNDS IN CHILDHOOD.

The author thought the best disinfectant was a one-third per cent. solution of salicylic acid, or for very septic wounds, a four to eight per cent. solution of chloride of zinc. One of the poorest materials for use in operations on children was carbolic acid. The general admissibility of corrosive sublimate solution (1 to 1,000) in childhood was, he thought, questionable. For certain wounds iodoform in small quantities is indispensable.

The best material for dressings was gauze impregnated with salicylic acid (five to ten per cent.) or corrosive sublimate (1 part per 1,000), while carbolized gauze was objectionable. Wood-wool cushions are of advantage for certain wounds. Dry dressings are best for fresh, as well as for large suppurating wounds, but for small suppurating wounds moist dressings are more suitable. In these, however, neither carbolic acid nor corrosive sublimate should ever be used.

In order to prevent soiling of the dressings with urine he favored covering them with a waterproof cloth, the

edges of the dressings being smeared with grease. Other methods of avoiding irritation from the urine were vertical suspension of the child. frequent changing of the dressings, or the permanent bath.

In concluding, the author pointed out the special indications for the employment of one or the other mode of treatment of wounds occurring in children.

Professor Jacobi, of New York, then presented a communication on

PRIMARY SARCOMA OF THE KIDNEY

in the new-born and in the young.

This was followed by a paper of Dr. Sophus Meyer, of Copenhagen, upon the

PROPHYLACTIC TREATMENT OF OPHTHALMO-BLENNORRHŒA NEONATORUM.

Ophthalmia neonatorum is an essentially dangerous affection, and measures of prophylaxis are therefore of especial importance. We do not yet know with certainty the cause of the disease, and we ought to encourage all investigations tending to elucidate this matter. Among the measures employed of late years, that of Credé may be considered the best. It is certainly a very satisfactory one, as, since its introduction into lying in institutions the malady has almost disappeared. Credé's method is not dangerous, and can be employed by midwives just as well as by physicians. The speaker concluded by urging upon his hearers the necessity of inducing midwives generally to make a constant use of the method in every case.

A paper was then read by Professors Hirschsprung, of Copenhagen, and Ribbing, of Lund, on

INTESTINAL INVAGINATION.

This condition was treated of as it occurs in children, and some remarks were made upon its comparative frequence in different countries. The authors endeavored to show that the great difference in this respect, as shown by the statistics of the several countries mentioned, was rather apparent than real.

Professor Faye, of Stockholm, followed with some remarks on

THE TREATMENT OF SCOLIOSIS.

At the conclusion of this paper the session adjourned.

Saturday, August 16th—Sixth Day.

In the morning a joint session of the Sections on Pediatrics and on Hygiene and State Medicine was held.

Two highly interesting papers were read by Mr. Malling-Hansen, of Copenhagen, and Dr. Vahl, of Jaegerspris, on the

NORMAL INCREASE OF WEIGHT IN ADVANCED CHILDHOOD.

The observations were made upon girls, from four to fifteen years of age, inmates of the Jaegerspris Asylum. The children were weighed in April and October of each year, from 1874 to 1883. It was found that the normal weight of girls at this age increases in regular progression from thirty-two and a half to ninety-eight and a half pounds (16.25 to 49.25 kilos). Up to the end of the fourteenth year the annual increment is eleven per cent. of the weight of the previous year, but after this time the rate of increase falls off somewhat. The increase during the six warmer months is greater than in the six colder months, in the proportion of four to three.

At the afternoon session Professor Medin, of Stockholm, read a paper on the

TUBERCULAR MENINGITIS OF EARLY INFANCY.

Tuberculosis, the speaker maintained, is frequent in the new-born, occurring sometimes in very severe epidemics, but tubercular meningitis is rare. Even epidemic cerebro-spinal meningitis is of more common occurrence in young infants. The author then spoke of the influence of age and sex and of the seasons, and pointed out the differences in the symptoms and course of the disease as it occurs in young infants and in children of a more advanced age. Tuberculosis of the meninges may occur, he said, without producing meningitis, and in such cases there are no symptoms by which the condition can be recognized. The paper was illustrated with a number of charts.

Professor Prévost then read a communication from Professor d'Espine, of Geneva, who was absent, on

A RAPIDLY CURABLE FORM OF INFANTILE SPINAL PARALYSIS.

At the conclusion of this paper

ADDRESSES

were made to the Section by the presidents, Professor Rauchfuss, of St. Petersburg, in French; Professor Jacobi, of New York, in English; and Professor Hirschsprung, of Copenhagen, in German.

According to the announcement of the last-named speaker, the labors of the Section were now concluded.

COMBINED SECTIONS OF ANATOMY AND PHYSIOLOGY.

Tuesday, August 12th—Second Day.

Professor v. Ebner presented a communication on behalf of Professor Rollet, on the

HISTOLOGY OF STRIATED MUSCLE.

The author of the paper believed that the primary element in the muscular fibre is the fibrilla, the Cohnheim fields being a section of a number of these fibrilla with an intermediate substance. This intermediate substance not only surrounds the fibrilla, but in some species there is a layer of it between the sarcolemma and the fibrillæ. There is a network of minute fibres which embraces the elements of which Cohnheim's fields are a section. The transverse disks are produced by this transverse network under the influence of the various reagents. The varied appearances observed in a muscular fibre are caused by the varying relations of the unformed substance, the fibrilla and this network.

In the discussion which followed the reading of this paper Professors Engelmann and Retzius stated that they agreed with the author on the main points in the paper.

Dr. Thin remarked that in all essential points the structure of striped muscular fibre, as described by the author of the paper, was that first expounded by himself in 1874, in two papers published respectively in the "Proceedings of the Royal Society" and the *Edinburgh Medical Journal*. The network described by Rollet in the paper just read, and also by Retzius in his monograph published last year, is the same as that described and figured by himself in the *Edinburgh Medical Journal*.

Professor Kronecker, of Berlin, then read a paper on

THE CENTRE OF CO-ORDINATION FOR THE MOVEMENTS OF THE VENTRICLES OF THE HEART.

The approximate position of this centre in the dog was, the speaker said, about one centimetre behind the descending branch of the left coronary artery. Injury to this centre stopped pulsation at once, irregular vibrations and twitchings alone remaining. By a series of experiments, Professor Kronecker has ascertained that this centre is neither inhibitory nor motor, but distinctly co-ordinating.

Dr. Gaskell, of Cambridge, read a paper on

INHIBITORY ACTIONS AND THE INHIBITORY NERVES IN GENERAL.

After referring in detail to the present views on inhibitory and excitor impulses in single nerve-trunks, and to Foster's experiments on direct inhibition of the cardiac

muscle of the snail, Dr. Gaskell described experiments on portions of the cardiac muscle of the tortoise, upon crocodiles in which the vagi had been mutilated, so as to insure complete degeneration of their cardiac periphery, and upon the cardiac nerves of frogs in which the vagus and sympathetic rami were completely isolated. Some recent experiments in the Cambridge laboratory were also quoted as entirely disposing of Foster's experiment upon the snail's heart. Dr. Gaskell's experiments, the record of which in the shape of most complete polygraphic tracings was shown, led him conclusively to state that muscle functions are not inhibited except through nerve stimuli. As to the condition of inhibited tissues or organs, whether the state is one of death or of increased potential energy, he emphatically expressed his opinion that the latter was the actual condition. He showed tracings of the cardiac contractions during stimulation of the sympathetic, after or during stimulation of the vagus, which supported him in this view.

SECTION ON DERMATOLOGY AND SYPHILIS.

THE ETIOLOGY OF LUPUS.

Professor Doutrelepont, of Bonn, opened the discussion by reading a paper in which he stated his belief that lupus is really a tuberculosis of the skin. Not only are the histological characters of the lupus nodules and the miliary tubercle very similar, but the specific bacillus of tuberculosis is found in both. The clinical course of the two diseases also presents, as he thought, some very marked points of resemblance—the slow course, for example, of some cases of phthisis, accompanied with many relapses. But the most important and most direct proof has been found in the inoculation of small pieces of lupus tissue into the cornea of rabbits, and the growth of distinct tubercle at the point of inoculation.

Dr. Leloir, of Paris, also read a paper dealing with the same points, and quoted a case of undoubted lupus of the bones, in which the disease resembled tuberculosis. He, too, had inoculated animals with lupus, and thereby produced tuberculosis.

Professor Kaposi, of Vienna, said that before the bacteria time it used to be remarked how unusually free from tuberculosis lupus patients were. He had seen 1,200 cases of lupus in twenty years, and had never seen any connection between the two diseases, although some patients had been covered with the lupus for many years. Real tuberculosis of the skin, of which he had seen fifteen cases, was a rare and entirely different disease, in which the actual miliary tubercles were seen plainly on the most superficial layers of the skin, and it was always rapidly fatal. Now, however, lupus, which is a perfectly clear and distinct clinical entity, has been confused with tuberculosis.

Professor Pick, of Prague, had long been led to suspect a close relationship between lupus and tuberculosis, but could not establish a satisfactory clinical identity. The discovery of giant cells at first promised to establish this connection, but the theory of their specificity was afterward disproved. The discovery of the bacillus tuberculosis had had a more satisfactory result. It had been found that the bacillus was always present in abundance in certain stages of the disease, and that this was the case even where no tubercular condition of other organs was present. Observers are, however, divided as to whether the bacillus is causal. Professor Pick considers that it is, and thinks that tuberculosis of the skin may exist as lupus vulgaris, as tuberculosis cutis of Kaposi, or in many other possibly not yet discovered forms, which may differ exceedingly, just as syphilides and gummata differ exceedingly, and which it may take a long time to distinguish and classify, as was the case with lupus and the serpiginous eruptions of syphilis. Although tuberculosis cutis is not lupus, lupus might still be, and probably is, a tuberculosis.

Professor Neisser, of Breslau, vigorously opposed Kaposi, the value of whose statistics he disputed, since the case had not been examined with a view to settling this question. There was a slow and a galloping syphilis, and there might be similar conditions in tuberculosis of the skin. He considered that the slow course and frequent recurrences in lupus were very like the course and relapses of tuberculosis, and this latter, too, like lupus, might last for years. Kaposi seemed to simply disbelieve in the bacillus tuberculosis, but with the present weight of scientific evidence on its side, Kaposi certainly would have to undertake the proof that lupus was not a tuberculosis in order to support his position.

Dr. Unna, of Hamburg, agreed with Doutrelepont and thinks with Pick that there are a series of bacilloses of the skin, all containing the bacillus tuberculosis. He knows of four such affections at the present time, viz., lupus vulgaris, tuberculosis cutis Kaposi, lupus papillaris Aubert, and scrofulous eczema, followed by caseous glands. He finds the bacilli are obtainable in quantity by partially digesting hardened specimens and examining the precipitate of what has fallen.

Professor Edward Lange, of Innsbruck, said that the murderous disease described by Kaposi did not correspond to ordinary mild, often curable, cases of tuberculosis. There was probably some form of skin tuberculosis which did so correspond, just as there were cases of carcinoma which were rapidly fatal, and cases which dragged on for decades.

Dr. Goldscheiden gave an interesting address on the

SPECIFIC SENSIBILITY OF THE SKIN.

He strongly supported Helmholtz's theory that every nerve, however excited, gave rise to only one specific perception in the cerebral ganglion cell with which it was connected. His investigations had shown him that there were only certain points which were capable of feeling heat, while a completely different and complementary set perceived only cold. It was immaterial how these points were excited, whether mechanically or by temperature change or electrically, the effect was the same; this fact, of course, refuted the old theory of perception of heat and cold by simple increase or decrease of the amount of heat in the nerve. These temperature nerves when excited give rise to no pain, nor do they possess any sensibility. Only certain "pressure points" possess acute specific sensibility, and outside these there exists only a diffuse indefinite perception. The points at which pain is appreciated are also quite distinct and very sensitive to various irritations. These pressure and pain points are always complementary to the points at which heat and cold are perceived. The touch nerves, like them, are always arranged in areolæ, and hence the necessity of passing the finger over any body which we are feeling, until an areola is met with capable of appreciating the shape and surface of the particular body. All these functions improve notably with education, as seen especially in the case of blind people. But there are many areas normally destitute of all appreciation of one or more of these different modes of sensibility.

Dr. Armauer Hansen, of Bergen, spoke at length on the etiology and pathology of lepra. He exhibited patients to show the difference between the tubercular form and the macular. The former was almost always fatal in nine or ten years, and the latter was often cured. The anæsthesia and atrophy which follow are effects of the healing process, not of the leprosy, and necrosis of the affected parts is always secondary to injury. The paralyses, too, are local; there are never any traces of spinal lesions to be found clinically or microscopically. He insisted that lepra was not an hereditary, but a specific contagious disease; the recurring crops of nodules showed its anti-inoculability, and since the growths tend to heal, it must be specific. There is, moreover, no anatomical correlation between the parts affected as in the metastasis of neoplasms. The cause of the disease had long been obscure. Years ago he had noticed

peculiar brown cells, which were always present in microscopic sections of lepra. In 1871 he described minute moving rods in the contents of a breaking down tubercle, and immediately after Koch's discovery he found the bacillus leprae by applying the same methods. He had never found them in anæsthetic patches, but Ahning has found them in anæsthetic nerves. The speaker and Professor Neisser have both cultivated them. Inoculation on rabbits and cats (Hansen), and on fish (Köbner and Hansen) had been unsuccessful, but Neisser had produced a new growth by inoculating a dog. No animal has, however, been lepraized as yet. He does not believe in the heredity of a contagious disease; a disease may be congenital without being hereditary, for example, small-pox. Heredity and the transmission of such a disease as syphilis are entirely different matters; the latter may develop late, and is incapable of atavism, etc. Relationship, even, with leprous people, is by no means always present. The inhabitants of a valley become in time all more or less related, and the members of one family naturally come into closer contact with each other than with outsiders, hence the apparent frequency of the spread among relations. Isolation is necessary, for although the disease is spontaneously curable, we cannot cure it; but the effect of isolating the cases in Norway has been effective in reducing the number of lepers by nearly one-half in twenty years.

Professor Neisser agreed in Hansen's views as to contagiousness and heredity in lepra. The spores which Dr. Hansen had spoken of were probably vacuoles.

Professor Pick read a paper on

EXCISION OF THE INITIAL SCLEROSIS IN SYPHILIS.

He confined his remarks to *hard* chancres, and distinguished carefully between those cases in which the glands were indurated and those in which they were not. Where the glands are affected they must also be excised, but in such cases, almost without exception, whether excision is practised or not, general symptoms make their appearance. The conditions under which the operation may be performed are only partially known. Simple excision of the sclerosis where the glands are affected will never give success, and no excision avails when the deep glands are swollen. Pick considers the effect on the therapeutics is but slight, mostly only a delay in the appearance of the general symptoms. The operation has, however, served to show that the indurated sclerosis is not the expression of general syphilis. The lymphatics have recently been found to be much enlarged in these cases, and Pick believes that the syphilitic poison passes into the organism through these, and not as Auspitz believes, entirely through the blood.

Dr. Unna, of Hamburg, believes that syphilis spreads not by any one path, but by both the blood-vessels, lymph-vessels, and by simple contiguity of tissue.

Professor Neisser, of Breslau, observed that although it was not yet certain by what path the syphilitic virus entered the system, still since it was a bacterial virus, there was no theoretical reason why it should not be prevented from entering by timely destruction of the bacteria.

Professor Bergh, of Copenhagen, gave accurate statistics extending over some years, and showing the comparative worthlessness of the operation as a protective measure.

Drs. Leloir and Barthelemy, of Paris, quoted most favorable cases in which excision, a few hours after the first appearance of the chancre, failed to prevent infection, and the latter stated that French opinion was now decidedly opposed to the procedure.

Dr. Martineau, of Paris, in opposition to the German speakers, regarded the chancre as a manifestation of general infection, and considered it, therefore, to be manifestly useless to excise it.

Professor Liebreich, of Berlin, in a paper on

THE TREATMENT OF SYPHILIS BY MERCURIAL INJECTIONS,

said he found that certain conditions were requisite in any mercurial compound which was to be subcutaneously injected, viz., it must not precipitate albumen, must be indifferent to the connective tissue of the skin, must not be decomposed by an alkaline solution, must be easily broken up, so that with sulphur sulphide of mercury is precipitated. Corrosive sublimate forms insoluble compounds with albumen, and which is only absorbed when these are broken up; it, moreover, breaks all the other conditions except the last. Tannates and citrates of mercury also unite with albumen and reach the blood in complicated combinations. A body which fulfils all these conditions is found in the formamide of mercury, which is easily prepared by precipitating the oxide by carbonate of ammonia and dissolving it in formamide. Amides of a number of other fatty acids also work well. If injected in quantity they form sloughs in the bowels during elimination (as does the sublimate) showing that they can work efficiently, the mercury in the compound being simply masked by the amide. They cause neither pain nor irritation of the tissues, and the dose is somewhat less than that of sublimate. It is, above all, important that the course of injections must be several times repeated; it is impossible to be sure of curing by one course alone. In the midst of the injections the case sometimes ceases to improve; the original vigor, however, can be rapidly restored by giving a good diet, with plenty of chloride of sodium, this salt and chloride of ammonium both assisting powerfully as "help cures."

Dr. Martineau said he had used injections exclusively in the treatment of syphilis for the last few years, and believed that it was the only reliable method, assuring a cure and causing no stomatitis or other alimentary troubles. In no case was the disease itself cured, but merely the manifestations, and in doing this, mercury injected subcutaneously occupied less than half the time required by the other methods.

There was a general consensus of opinion among the after speakers that the injection of mercurials was a valuable method of treating syphilis, but by no means the only one. No one method suited all cases. Meisser thought that the injections should be smaller and more frequent, and considered that the formamides eliminated too quickly.

Professor Doutrelepont said he does not believe formamide to be absolutely the best form for injection. All salts when injected in a sufficient therapeutic dose, may cause stomatitis.

Dr. Shoemaker, of Philadelphia, after prolonged experiments on the various methods of injecting mercury, had come back to the simple solution of sublimate in water, as the most effectual and least irritating.

Dr. Wulff, of Strasburg, had made and injected the formamides five years ago. He always used them perfectly freshly made from triturated solutions; they then work quickly and well.

Dr. Unna advocated the use of keratinized mercurial pills, which dissolve in the alkaline juices of the small intestine, leaving the stomach untouched; in this way the irritation caused by injection may be avoided.

Dr. Barthelemy always used the peptones for injection and found that they acted quickly, but believed that pills were by far the best and simplest method for continued treatment.

Professor Kaposi found injections useful, but considered that inunction was by far the quickest and most vigorous method of cure.

Most of the speakers considered that although statistics were a valuable help in deciding the relative merits of the different methods of cure, especially the statistics of venereal hospitals for prostitutes, yet the judgment of the relative merits of different methods depended mostly

on the good clinical observation of the individual experimenter.

INOCULATION OF SYPHILIS IN ANIMALS.

Dr. Martineau had successfully inoculated a monkey with syphilis and produced a distinct chancre, erosive and ulcerative syphilides of the skin and pharynx, and hypertrophic papular syphilides of the scrotum and thigh.

Professor Pick had seen the monkey which Klebs claimed to have syphilized. He was only acquainted with syphilis in the human subject, but the eruption which broke out in the monkey looked to him more like a varicella accidentally inoculated, than like any syphilitic eruption in man.

PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, June 6, 1884.

Samuel Sexton, M.D., President, *pro tem.*

Dr. Wm. T. Lusk read the paper of the evening, entitled:

SUDDEN DEATH IN CHILDBIRTH.

The case illustrating such had the following history: The patient was a primipara, healthy, and twenty-three years of age. I first saw her January 1st of present year at 7 A.M. Patient said pains had begun on previous afternoon, and she had paced the floor all night. She said that when in motion she found it easier to bear her pains. Examination: Extreme tenderness of vagina and cervix; cervical canal dilated by head, os extended, size of half dollar; head covered tightly by membranes, no pouch. At 11 o'clock little progress. Gave chloroform and pushed up head so as to allow bag of waters to form. This manœuvre was followed by rapid dilatation. Head in twenty minutes on perineal floor. I then urged forceps. Patient wished "glory of having her baby herself." Waited at her instance until between 1 and 2 o'clock. Patient suddenly lost color and seemed dazed when spoken to. Applied forceps to head at vulva. Easy extraction followed by some hemorrhage, but the latter was quickly controlled. Patient's face showed signs of complete collapse. Stimulants, warm hypodermics of brandy, and hot tea were given at short intervals. Apparent rally. At 7 P.M. went to dinner, thinking period of safety reached. Patient suddenly turned in bed, and pulse became very feeble. There was a slight rally, and then came death. Absence of respiratory troubles excluded pulmonary embolism either from venous thrombi or from air. The associated symptoms were those of surgical shock, to which the patient was probably predisposed by the ante-partum exhaustion. The writer argued against the rejection of surgical shock among the causes of sudden death in childbed, holding that the entry of air into veins, embolism, and pulmonary thrombosis are insufficient to account for all cases.

Dr. G. F. Shrady mentioned two cases which had just been published in The Medical Record, and in which death, as he thought Dr. Lusk would agree, was due probably to shock. He had seen in journals the reports of two other cases within the last six months.

Dr. Lusk remarked that text-books on obstetrics assumed that it was not possible for a woman to die of shock in parturition, but from what he had observed, he was inclined to believe that death in lying-in women was not infrequently produced by that cause.

Dr. Shrady thought that death in Dr. Lusk's case was best explained on the supposition that it was produced by shock; for the phenomena were exactly what occurred in surgical practice from sudden loss of blood in a nervous patient.

Dr. Dana asked if the patient's heart was examined.

Dr. Lusk said he examined the heart and did not find any sounds to indicate the presence of cardiac disease, and the patient was so young and had enjoyed such perfect health that he thought any change affecting the muscular structure of the heart could be reasonably excluded.

Dr. Dana asked if any pathological evidence had been obtained to sustain the view that shock was due to paralysis of the splanchnic nerves.

Dr. Lusk replied that the view was the result of experiments on animals.

Dr. Dana thought that experiments on animals proved just the opposite, because when these nerves were completely divided, causing paralysis of the blood-vessels supplying these viscera, the animals do not die.

Dr. Lusk said the experiments were performed by striking upon the abdominal walls, producing paralysis of the blood-vessels and withdrawal of blood from the heart.

Dr. Dana remarked that striking the abdomen, especially when the peritoneum was inflamed, might stop the heart, but it did so by affecting certain sensory nerves.

Dr. Ball asked if the effect was not too sudden to account for it upon the supposition of withdrawal of blood from the heart.

Dr. Lusk remarked that he did not feel called upon to defend the theory of the production of shock, but in the most recent articles on shock the theory of Fisher was that which had been adopted, and to him shock as a cause of death in the cases under consideration seemed to be the most reasonable explanation which had been offered.

Dr. Dana asked further if it was not a clinical fact that death had occurred with chloroform some time after the anæsthetic had been removed.

Dr Lusk said that such cases had been reported, but he was not aware that any had been reported in which death occurred after the patient had regained complete consciousness, and during the administration showed no undue sensitiveness to the anæsthetic. It had been suggested by Dr. Delafield that this was the explanation of sudden death in these cases, but on looking over the literature of the subject, Dr. Lusk had found that the cases occurred so much more frequently before chloroform was introduced into obstetric practice than they had since that the fact seemed to disprove the supposition that death was due to chloroform.

In Dr. Lusk's case there was an interval of two hours between the first and second administration, and during this interval the woman was perfectly conscious and gave no evidence that she had been unduly affected by the chloroform; at the first it was administered in moderate quantities for half an hour, and at the second administration it was given for fifteen minutes.

Dr. E. L. Partridge alluded to two cases of sudden death following labor. One was a case in which the woman died suddenly on the twelfth day after confinement without any unfavorable symptoms during the puerperal period, except a moderate cellulitis, from which she recovered promptly, all the symptoms disappearing, and the pulse and temperature becoming normal. One morning, while the nurse and physician were standing at the bedside, just after the pulse had been noted at 88 and the temperature 99° F., the patient asked for a drink of water in the usual way, and within ten minutes was dead, without a symptom or movement. The pulse continued to beat two or three moments after respiration ceased.

The autopsy revealed an abscess of the cerebellum. The patient had had ear trouble, without discharge or anything to direct attention to it during her stay in the hospital (Nursery and Child's). It was not supposed that parturition had anything to do with the abscess in the cerebellum. But the case was interesting as an illustration of the fact that parturient women can die from causes other than those connected with the process of labor.

In the other case, the woman died of shock and nervous prostration following tedious labor. The forceps were applied early; there was no hemorrhage, but the

woman died within twenty-four hours. At the autopsy nothing was found to explain the sudden death.

In absence of post-mortem examination he would not be willing to say that death in Dr. Lusk's case was due to shock; and at the same time he did not feel willing to say that she did not die of shock.

Dr. Lusk said he assumed that a woman who took no rest for the length of time his patient abstained from it must necessarily place herself in an unfavorable condition, and he had believed that such symptoms were due to exhaustion.

Dr. A. A. Smith narrated a case as follows: In the year 1873 he was asked to attend a young woman in confinement. He promised to visit her on a Tuesday. The mother sent for him on Monday afternoon, and when he arrived he heard the following history: On Saturday afternoon the patient reached up to pull the window down, and, as she did so, she felt something give way, and was seized at once with sharp pain in the lower part of the abdomen. She sat down in a chair for a short time, but, not feeling very well, went to bed. On the following day she felt tolerably well, but on Monday Dr. Smith was sent for on account of sharp pain and quite free hemorrhage. Vaginal examination revealed the fact that labor had begun, and the case progressed very well up to three hours afterward, when the woman began to complain of feeling weak, and, although the child's head was quite well down in the pelvis, there seemed to be a tumor of considerable size above. He was unable to obtain sufficient evidence to make it certain that there was internal hemorrhage, but delivered the woman at once of a child weighing six and a-half pounds, and with the delivery there was rise of pulse and evidence of hemorrhage, as shown by one great gush of blood with the delivery of the child. No further hemorrhage occurred, but the woman died within an hour after the birth of the child, as the result of exhaustion and shock caused by antepartum loss of blood. Dr. Smith believed that if he could have diagnosticated ante-partum hemorrhage he could have saved the patient's life by the hypodermic injections of ergot and atropia, etc.

SUCCESSFUL OPERATION FOR EXSTROVERSION OF THE BLADDER.

Dr. George F. Shrady presented a diagram which illustrated the successive steps in an operation he had performed at the Presbyterian Hospital, in a case of exstroversion of the bladder.

The patient was a male, five months old. A triangular skin-flap with its apex just below the umbilicus was dissected downward to the upper surface of the exposed posterior wall of the bladder and turned downward like the leaf of a book, the base of the flap being left attached. By this means the exstroversion was completely covered, leaving two raw triangular surfaces exposed with a common base. One of these surfaces was the bed of the flap, and the other the posterior surface of reversed flap itself. To cover the raw surface of the reversed flap a quadrilateral flap, looking downward and inward, including skin from the lower portion of abdomen, groin, and sides of the scrotum, was made on either side and turned inward so that the lower and free extremities of each could be joined in the median line. The triangular raw surface of the bed of the reversed flap above was converted into an inverted T-shaped wound by loosening the basal angles of the raw surface and joining them in the median line. The beds of the quadrilateral flaps in the groin, which were triangular in shape, were also converted into T-shaped wounds by carefully sliding the opposing edges toward each other.

The reversed flap was first sewed in position, completely covering in the bladder, one thread of each suture being left long so as to be brought out externally from between the edges of the superimposed flaps. The quadrilateral flaps were then sewed in place, and then the upper raw surfaces and the beds of the quadrilateral flaps were closed as indicated.

The wounds healed by first intention, except at one unimportant point, which subsequently closed by granulation, and the child made a perfect recovery, the urine escaping only by a small opening over the pubes.

A condition of epispadias existed, which Dr. Shrady intended to remedy by subsequent operations when the child was old enough to warrant them.[1]

EXTRA-UTERINE PREGNANCY.

Dr. Charles S. Ward presented the child and placenta removed by operation in a case of extra-uterine pregnancy, with the following history. Mrs. B——, twenty-three years of age, the mother of one child, and no miscarriages. Her child was born four years ago, and the labor was normal. Her menstrual history was normal until last July, when a slight show became constant until lately. She first noticed enlargement of her abdomen in August last. The abdomen gradually increased in size, and movements were first noticed in September, and ceased in March last. The woman thought she was at full term in March. During the last three months she had had aching in the pelvis. The mammary signs were normal until last March. During the last three weeks she has lost flesh. Dr. Thomas diagnosticated abdominal pregnancy when he saw the woman in March. He performed laparotomy June 5th, and removed the fœtus with a part of the placenta. The abdomen presented the appearance of that of a woman in the *seventh* month of pregnancy. On palpation, an elastic tumor could be felt, and per vaginam the uterus could be recognized as anteverted, somewhat enlarged, with a cervix normal to the touch, and ballottement was absent. Neither was there any body to be detected, except by the fact that something filled the superior strait of the pelvis. Up to three months ago the woman believed that she was pregnant. Except for the extreme degree of pigmentation of the abdominal walls, Dr. Ward would have felt sure that extra-uterine pregnancy did not exist.

On making an incision through the abdominal walls in the median line, he reached first a brownish-black looking body, which presented very much the appearance of the liver. After opening the membrane about a quart of fluid, resembling molasses and water poured out, and in passing his hand in Dr. Thomas was able to seize a leg and delivered a child weighing nine pounds. It was the sixth case which Dr. Ward had seen operated on, and the next step of special interest pertained to the management of the placenta, which presented the appearance of a cup covering the entire anterior surface of the growth, and looking very much like the liver, both in color and contour, and giving very much the feel of the liver. It was attached to the ileo-pectineal line on the right side, extended upward under the diaphragm, and dipped down into the pelvis on the left side. The placenta was partially removed by tying it off in sections from its attachment to the pelvic rim, omentum, and intestines, and this was accomplished with comparatively a small amount of hemorrhage.

The question concerning the advisability of leaving the after-birth was raised. In some of the cases it had been allowed to remain and to discharge from the opening in the abdominal wall; but it was probable that such a mass, weighing several pounds, could not be discharged, and it was determined to remove a portion of it at least, if it could be detached from the intestines and omentum so as to avoid hemorrhage, as the part attached to the pelvic brim could be secured so as to avoid special danger from that source. The remaining portion of the placenta was sewed to the abdominal wound, and an open-

[1] The child continued to do well for two months after the operation, and was altogether in a very satisfactory condition, when during the heated term of the present summer it was seized with cholera infantum, dying of the disease in one week. No autopsy was obtainable.

ing left for drainage. Thus far the patient was doing well.

Dr. Lusk had a case, a short time ago, in which diagnosis was very puzzling. The patient came to him with a note from her physician, who said that she was unmistakably pregnant, but that all the symptoms had disappeared. Dr. Lusk found that there were no special symptoms of pregnancy, and the patient soon afterward left the hospital. She returned two months ago, when it was found that the tumor had increased in size. Dr. Lusk then introduced a needle and withdrew considerable pus. He then regarded the case as one of pyosalpinx, and proceeded to operate. After exposing the mass and tying off the omentum, he endeavored to detach the tumor, which was embedded in the pelvis and extended between the bladder and the rectum, and on lifting it up and working his fingers down by its side they passed directly into the rectum. He soon found that it would be impossible to enucleate the mass, and therefore cut into it, when he found a very marked thickening of the decidua, and inferred that it was a case of tubo-ovarian pregnancy, although he was unable to find any trace of the embryo. He then emptied the sac, stitched its walls and the peritoneal growth to the edges of the abdominal wound, and the patient did very well. The sac gradually closed, the wound had been reduced to small size, and the patient was sitting up in the ward.

The Society then adjourned.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, September 22, 1884.

David Webster, M.D., President *pro tem.*

CANDIDATES FOR MEMBERSHIP.

The *Comitia Minora* recommended for membership Drs. A. K. Hills and A. T. Hills, graduates of Homœopathic Medical Colleges. On motion the recommendation was referred back to the *Comitia* for further investigation.

NOMINATION OF OFFICERS.

The following nominations were made for officers for the ensuing year:

For President—Drs. Daniel Lewis, Henry B. Sands, D. B. St. John Roosa, and Andrew H. Smith.

For Vice-President—Drs. Frank P. Foster and Laurence Johnson.

For Secretary—Dr. Wesley M. Carpenter.

For Assistant Secretary—Dr. Charles H. Avery.

For Treasurer—Dr. Orlando B. Douglas.

For Censors—Drs. J. W. Howe, F. R. S. Drake, W. O. Moore, F. M. Weld, A. S. Hunter, H. E. Crampton, H. T. Peirce, J. H. Ripley, and W. R. Gillette.

Dr. A. Jacobi then read a paper on

INFECTIOUS DISEASES IN THE CHILDREN'S SERVICE OF BELLEVUE HOSPITAL,

and directed special attention to typhoid fever and diphtheria. It will appear in a subsequent number of The Record.

The paper was discussed by Drs. G. B. Fowler, C. H. Knight, M. B. Feeney, E. H. M. Sell, A. Seibert, and the discussion was closed by Dr. Jacobi.

Dr. R. Van Santvoord, Secretary, read a report from the Committee on Hygiene on

THE FREE BATHS OF THE CITY OF NEW YORK,

in which attention was directed to their usefulness and the urgent necessity for a greater number was pointed out.

The report was accepted and its recommendations adopted.

PROPOSED AMENDMENTS TO THE BY-LAWS.

Any member neglecting to pay dues and assessments for two years, shall forfeit his or her membership, provided he or she shall have received from the Treasurer one month's notice of his or her delinquency. Such member may be reinstated upon the recommendation of the *Comitia Minora* after the payment of his or her arrears.

Stated meetings shall be held on the fourth Monday of every month, except in the months of June, July, August, and October (annual meeting).

Dr. John L. Vandevoort was nominated for honorary membership.

ABUSE OF MEDICAL CHARITY.

The Secretary read a communication received from Dr. W. H. Donaldson, Secretary of the Bridgeport Medical Society and of the Fairfield County Medical Society, Connecticut, directing attention to the fact that many persons who were abundantly able to pay physicians' fees came from that locality to New York and obtained gratuitous medical advice at hospitals and dispensaries in the city of New York.

The communication was received and referred to a committe of three, Dr. A. Jacobi, Chairman, to be reported on at some future meeting.

The Society then adjourned.

Correspondence.

SOME OBJECTIONS TO THE USE OF PEPTONIZED MILK IN THE FEEDING OF INFANTS.

To the Editor of The Medical Record.

Sir: The importance of the subject of the artificial feeding of infants, and the difficulty of finding an efficient substitute for mother's milk may, I trust, prove sufficient excuse for my transgression on your valuable space. Since the publication of your editorial and the communication of Professor J. Lewis Smith in regard to the above subject, I have adopted the plan therein recommended for peptonizing milk, and I would ask correction on the following points: Casein, being an albuminoid, is largely acted upon in the stomach and absorbed directly from that viscus, and only those portions which *may* escape into the intestine are acted upon by the pancreatic secretion. It seems rational that the immediate coagulation of the casein in the stomach is to prevent its passage through the pylorus until acted upon by the pepsin of the gastric secretions in presence of an *acid*. By introducing an excess of alkali with the milk the gastric secretion is rendered inert (for the time being) and the milk does not coagulate, but passes on into contact with the secretions of the pancreas, small intestine, etc., where it is only *partially* converted into albuminose. Stomach digestion is, by this plan of management, practically "eliminated." The milk, instead of being retained for several hours, as it is in the stomach (normally), in direct contact with the gastric ferment, passes (too rapidly?) on through the intestine. In patients with "intestinal catarrh," fed on peptonized milk, some of the dejections consisted of two nearly distinct portions: a greater or less amount of mucus and a perfectly homogeneous mass of putty-like, partially digested casein. The quantity of food allowed was one fluid ounce every four hours; Fairchild's pancreatin was used, with Squibb's sodium bicarbonate, five grains of the former to fifteen grains of the latter, the details of the process as published having been carefully carried out. In cases in which vomiting is not troublesome, would it not be rational to confine digestion to the stomach, as far as possible, with the object of relieving the inflamed intestine? I am induced to make these crude suggestions in the hope that a "weighty word" may be elicited in reply. Very respectfully,

N. E. Oliver, M.D.

THE USE OF PEPTONIZED MILK FOR INFANTS.

To the Editor of The Medical Record.

Sir: There is a practical objection to the use of peptonized milk for infants in the manner that has been suggested by Dr. Smith and others. It consists in the fact that young infants have to be fed in the middle of the night. Now a sleepy mother, however affectionate, will not be disposed to get up at 2 A.M., prepare the milk, warm the water, and wait twenty minutes for the mixture to digest, while the infant *ad interim* howls, wakes up the male parent, and disturbs the household generally.

I would inquire whether a little pepsin containing the curdling ferment or a little gelatine will not do just as well. Also, whether the casein in condensed milk does not coagulate in fine flakes. Certainly I have found condensed milk to nourish children admirably, despite its sweetness. Yours, very truly, M. S.

Philadelphia, September 3, 1884.

THE NORTH CAROLINA CLIMATE FOR CONSUMPTIVES.

To the Editor of The Medical Record.

Sir: Physicians are sending consumptives from the Northern and New England States to California, Colorado, Texas, and Florida, when there is a more accessible and equally efficacious region much nearer. I refer to Western North Carolina, of which region Asheville, Buncombe County, is the metropolis, railroad centre, and great health resort for winter and summer. Fifteen years ago my father, Dr. H. P. Gatchell, Sr., wrote a pamphlet on this region, from which I get my facts regarding the climate. Asheville is 2,250 feet above tide-water; it is a place of five or six thousand inhabitants. It has six hotels and boarding-houses, capable of caring for twenty-five hundred guests. There is a club-house, a public library with free reading-room, and there are the usual churches and schools found in a place of this size. The climate of Asheville compares favorably with that of Geneva in Switzerland, Turin and Milan in Italy, and Vienne in the valley of the Rhone, East France.

	Spring. Temp. deg.	Summer. Temp. deg.	Autumn. Temp. deg.	Winter. Temp. deg.	Year. Temp. deg.
Geneva..	52.2	70.3	54.2	34.0	52.7
Turin....	53.7	71.5	53.8	33.5	53.1
Asheville.	54.3	71.3	55.3	37.8	55.3
Vienne ..	56.2	71.8	54.6	38.7	55.3
Milan ...	54.9	72.8	55.9	36.1	54.9

From the above table it may be seen that the winter climate of Asheville is milder than any of the places with which it is compared except Vienne. This place is enjoying a wide reputation as a resort for the cure of incipient phthisis. The writer has known of not a few complete recoveries, and many desperate cases which greatly improved. To show the immunity of this region from pulmonary disease, I append the following table. Out of every 1,000 deaths there are from consumption

In Northern New England (nearly).....	250
In Minnesota and California.....	150
In Kentucky and Tennessee (nearly)...	100
In Louisiana and Florida.....	50
In Western North Carolina.....	30

Dr. Cain, formerly of Charleston, S. C., says that not one of the many consumptives, in different stages of the disease, that he has sent to Asheville, has failed to improve; and he regards it as the most healthful country in the world.

The distinguished Professor Dickson, of Jefferson Medical College, stated that he and his family nowhere improved so much as in Asheville. He is "not aware of any spot, in Europe or America, so full of all that is desirable."

Dr. S. E. Chaillé, of New Orleans, who spent from three to five months in this region annually for four years, wrote that he had seen but one case of consumption, a mulattress, and not a native of this section The above is taken from an article by Dr. Chaillé, which may be found in the *Medical and Surgical Reporter* for April, 1878, p. 269; and in which he gives the results obtained at this place by Dr. W. Gleitzman in his *Sanitarium;* he stated that every incipient case of consumption was cured, or the disease arrested and the patient so much improved that it was safe to say that the improvement would go on to complete cure under the same conditions.

The scenery is grand and picturesque. On the Western North Carolina Railroad there are feats of engineering, and bits of scenery surpassing anything in the mountains of Pennsylvania, and equalled, perhaps, nowhere in the country.

The people are kind and hospitable, and life and property are as safe as in any section of the United States.

Edwin A. Gatchell, M.D.

Asheville, N. C.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 14 to September 20, 1884.

Caldwell, D. G., Major and Surgeon. Granted leave of absence for one month and twenty days, to commence about October 15, 1884. S. O. 95, Headquarters, Division of the Missouri, August 16, 1884.

Cronkhite, Henry M., Captain and Assistant Surgeon. From Department of the Platte to Department of the Missouri. S. O. 215, par. 1, A. G. O., September 13, 1884.

Taylor, Arthur W., First Lieutenant and Assistant Surgeon. From Department of the Missouri to Department of the Platte. S. O. 215, par. 1, A. G. O., September 13, 1884.

Wilson, William J., Captain and Assistant Surgeon. From Department of Dakota to Department of the East. S. O. 220, par. 1, A. G. O., September 19, 1884.

Gardiner, J. de B. W., Captain and Assistant Surgeon. From Department of Arizona to Department of the East. S. O. 220, par. 1, A. G. O., September 19, 1884.

Corbusier, William H., Captain and Assistant Surgeon. From Department of the East to Department of Arizona. S. O. 220, par. 1, A. G. O., September 19, 1884.

La Garde, L. A., Captain and Assistant Surgeon. From Department of Missouri to Department of Dakota. S. O. 220, par. 1, A. G. O., September 19, 1884.

Barrows, C. C., First Lieutenant and Assistant Surgeon. Granted one month's leave of absence, with permission to apply to the proper authority for an extension of one month. S. O. 86, par. 4, Headquarters Department of Arizona, September 13, 1884.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 20, 1884:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.

Original Articles.

THE THREE TONSILS—SOME PRACTICAL SUGGESTIONS IN REGARD TO THEIR STRUCTURE, FUNCTION, AND DISEASES.[1]

By F. H. BOSWORTH, M.D.,

PROFESSOR OF DISEASES OF THE THROAT IN BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK.

I INVITE your attention this evening to a consideration of the three tonsils, in order that I may bring forward certain views in regard to them which I have for some time entertained, and which, while contrary, I think, to the generally accepted opinion, will, if true, serve to clear up much that is vague in the prevailing views as to the functions of these glands, and also to give a more practical direction to our therapeutical measures in the management of many of the commoner forms of disease in the fauces.

By the three tonsils it is to be understood that I refer to the two glandular masses found between the pillars of the fauces, and to which the name tonsil is usually applied, and to that mass of glands which is found in the vault of the pharynx, and which was first recognized and described by William Hunter,[2] and subsequently, and to a fuller extent, by Luschka,[3] and to which the name of Luschka's tonsil has been given, and also that of *the pharyngeal tonsil.* These three masses being so nearly identical in their structure, function, and diseases, I think that they may be properly designated as the three tonsils. The masses between the pillars of the fauces will be spoken of as the faucial tonsils, while that structure at the vault of the pharynx will be designated as the pharyngeal tonsil.

It has been the custom to describe the faucial tonsils as "two almond-shaped organs lying between the pillars of the fauces, and covered by a fibrous investing membrane or sheath, in which are from seven to twelve openings, which mark the orifices of a number of mucous glands, of which the organs are composed." There are, I think, several sources of error in this description. The faucial tonsil is not covered by a fibrous sheath. Underlying it there is a more or less dense connective-tissue layer, which is continuous with the submucous layer which underlies all mucous membranes. Beneath the mass this is thickened by the same morbid process which has developed the tonsil. Further than this there is no sheath to the gland. It is not an almond-shaped organ as a rule, but is of whatever shape the morbid process which has caused its growth may give it. The number of openings on its surface is entirely dependent upon the number of the glands which are involved in the hypertrophic processes which have produced it. It is not an organ of the body in the sense that the liver and spleen are organs, and which I think is a commonly accepted view, and therefore, in this sense, has no especial function to perform in the economy. In my work on "Diseases of the Throat," published three years ago, I subjected myself to criticism by the assertion that in the healthy throat there are virtually no tonsils. This opinion I still entertain. The "almond-shaped organ," etc., described by anatomists does not exist in a healthy throat, but is the result of a morbid process. This morbid process may have been of such limited extent as to have developed but a small tonsil, and one not sufficient to give rise to any other than trivial symptoms; or it may have gone to the extent of developing a mass of sufficient extent to cause serious disturbances. All mucous membranes are richly endowed with glands, in order that they may be kept in that soft and pliable condition which the proper performance of their functions demands. Perhaps no portion of the mucous tract demands a greater supply of mucus in the performance of its functions than the upper air-tract. In this region, therefore, we find these muciparous glands not only richly distributed throughout the membrane, but also aggregated in masses. This tendency to aggregation is especially noticeable in the pharyngeal vault, and between the pillars of the fauces. In a condition of health these aggregations of glands do not project prominently from the membrane, and hence, in a perfectly healthy state, their existence is not easily demonstrated by gross inspection.

The mucous membrane of the upper air-passages, however, perhaps more than any other portion of the body, is liable to be the seat of morbid action. It is a very noticeable clinical fact, also, that while in adults it is the mucous membrane proper which is most liable to be the seat of disease, in children it is the glandular structures which are especially susceptible; hence we find that morbid conditions of these glands, both in the fauces and in the pharyngeal vault, are of exceedingly frequent occurrence, especially in children.

The tendency of chronic inflammatory processes is to develop in hypertrophy. Hence we find a moderate hypertrophy of these glandular masses of exceedingly frequent occurrence in young people, constituting in the one case so-called enlarged faucial tonsils, and in the other an enlarged pharyngeal tonsil.

In order to make clearer my meaning, I will very briefly allude to the anatomy and functions of the upper air-tract. The nasal cavity proper extends from the nostrils in front to the posterior nares behind. They are lined by mucous membrane covered with columnar ciliated epithelia, whose ciliæ move in a direction from behind forward. These cavities fulfil a double function: they contain the distribution of the olfactory nerve and preside over the function of olfaction. With this we have nothing to do in the present consideration. The other function consists in guarding the entrance to the lungs, warming, moistening, and cleansing the inspired air. For the latter purpose the nasal mucous membrane is very richly supplied with glands which pour out an abundant sero-mucus, by which the inspired air becomes charged with moisture. The nasal cavities, then, belong purely to the air-tract. Behind the nasal chamber lies the pharynx. This is usually described as one cavity, extending from the basilar process of the occipital bone to the œsophagus. There is, I think, a source of error in this. That portion of the pharynx which lies above the border of the soft palate is lined with a mucous membrane covered with columnar ciliated epithelia, and very richly endowed with muciparous glands, those in the vault constituting the pharyngeal tonsil. Below the border of the soft palate the pharynx is lined with a mucous membrane, which is covered with pavement epithelia and very scantily supplied with glands. The characteristic anatomical feature of the air-passages is that they are lined with a mucous membrane covered by columnar

[1] Read before the New York Academy of Medicine, October 2, 1884.
[2] Cohen: Diseases of the Throat, second edition, p. 253.
[3] Der Schlundkopf der Menschen.

ciliated epithelia, and richly endowed with mucous glands; a form of mucous membrane which, while exceedingly delicate and sensitive, is eminently adapted to its function. It tolerates the passage of air, corrects its temperature, regulates its humidity, and prepares it for the lungs. At the same time it resents the impact of any foreign body, harsh substance, or the entrance of any irritating gas or vapor. It is also endowed with glands which secrete a more fluid mucus, more of the character of a sero-mucus.

On the other hand, the food-passage is lined with a mucous membrane which is covered with squamous epithelia. Its function is to allow the passage of masses of food of oftentimes firm consistence, but whose impact upon the membrane of the air-passage would not be tolerated. For this purpose the membrane is so constructed that it is hard, dense, and resisting, and not especially sensitive. It is richly endowed with glands which pour out a viscid mucus, whose function is as a lubricant mainly.

The pharynx, then, as it is usually described by anatomists, is really composed of two cavities differing materially in structure and function. The upper pharynx belongs to the air-tract, while the lower pharynx belongs to the food-tract. This view is still further sustained by the fact that an inflammatory process in the one region does not involve the other as a rule. A pharyngitis involving the lower pharynx is, I think, a very rare disease, and when met with, is not connected with any morbid condition of the upper pharynx, but rather with some disturbance of the food-tract, such as a gastritis, etc.

The lower pharynx, as before remarked, is very scantily supplied with glands, and yet in the performance of its functions it demands an abundant supply of mucus, in order that it may be kept sufficiently lubricated to allow of the easy passage of food in deglutition. Gland structures are exceedingly delicate, and liable to injury on exposure. The lower pharynx is perhaps the most exposed region of the mucus tract; it is therefore a hard, dense membrane with but few glands. In order to compensate for this deficiency it is surrounded on three sides with large aggregations of glands, one on either side between the pillars of the fauces, another immediately above in the vault of the pharynx, constituting in the one case the faucial tonsils, in the other the pharyngeal tonsil. The sole and only function of these masses of glands which constitute the three tonsils is, I believe, to supply mucus to moisten and lubricate the lower pharynx, and the design of Nature in so locating them has been most wise, for had the lower pharynx been endowed with glands sufficient for its demands, disease occurring in them would be attended with far graver consequences than attend morbid conditions of the gland arranged as we find them.

The minute anatomical structure of the faucial and pharyngeal tonsils have been so often described that further allusion to them need not be made. Their resemblance is so clear that the only difference in structure is easily accounted for by the fact that the pharyngeal tonsil is protected from any impact of foreign substances, and is therefore of a soft and spongy consistence, and contains connective tissue, less in amount and less firmly organized than the faucial tonsils, which are subjected to much harsher usage in the act of deglutition.

From a pathological point of view we find still further grounds for grouping the three tonsils together, for the same morbid processes which occur in the faucial tonsils are met with in the pharyngeal tonsil. These are: acute inflammation; chronic inflammation, resulting in hypertrophy; acute follicular inflammation; croupous inflammation, and diphtheritic inflammation.

Acute tonsillitis is a name generally given to quinsy. I shall endeavor to show later that quinsy is not a disease of the tonsil, but is an inflammation of the cellular tissue of the soft palate or neighboring parts, and that phlegmonous inflammation does not occur in the tonsil. As a matter of fact, therefore, the only form of acute inflammation met with in the tonsil is a catarrhal inflammation, viz., one attended with hyperæmia, swelling, and hypersecretion. This is usually described under the term subacute inflammation. In deference to common usage, therefore, I use the usual nomenclature.

Subacute tonsillitis.—This in the faucial tonsil consists of a mild form of inflammatory action characterized by swelling and hyperæmia of the glands, and is the result, generally, of exposure to cold. The constitutional disturbance is not great, there being, as a rule, a mere feeling of general malaise with chilly sensations. The tonsils are swollen to twice or three times their size in the quiescent state, and project into and encroach upon the isthmus of the fauces, two red, angry-looking masses. The palate may be involved in the hyperæmia, but there is no notable swelling beyond the tonsil proper. The attack is not of any serious import, and runs its course in from four to seven days. The predisposing cause is enlarged tonsils, and it occurs in children more frequently than in adults, simply for the reason that in children enlarged tonsils are most frequently met with. *Subacute tonsillitis* occurs in the pharyngeal tonsil with the same frequency as in the faucial tonsil; it is attended by the same constitutional symptoms, a mild febrile disturbance, and no more; and it is caused, as a rule, by exposure to cold. The main predisposing cause is an enlarged pharyngeal tonsil. It occurs most frequently in children, runs its course and subsides in the same way as the faucial disease. The only difference in the two affections is in the symptoms, which differ merely from the location of the morbid process. As far as I know, the affection has never been described under the above heading, although Meyer, in his original article on "Adenoid Vegetation in the Naso-pharyngeal Cavity,"[1] described their tendency to sudden attacks of turgescence, by which their size varied greatly at different examinations.

Löwenberg[2] and other writers allude also to the same symptom. It will be easily understood how, in the case of a mild inflammatory process occurring in the pharyngeal tonsil, the symptoms will be mainly nasal. There is apparently a cold in the head. The nasal passages are obstructed, the voice becomes affected, changing to what Meyer calls the dead voice, its nasal resonance is destroyed, and there is more or less discharge of mucus or muco-pus into the fauces. The attack is what is usually regarded as a cold in the head, and is often called an acute coryza. This, I think, is a frequent error. An acute inflammation of the nasal mucous membrane in children is very rare. As before remarked, the glandular structures are the parts generally attacked in children and not the mucous membrane proper, and their colds, if in the throat, are in the faucial tonsils, and if in the nasal passages, are in the pharyngeal tonsil rather than in the nasal membrane. The attack subsides in a few days, as in the faucial disorder, its frequent recurrence, however, should call attention to the probable existence of the chronic disorder which is in most cases the predisposing cause of the attack.

Acute follicular tonsillitis.—The epidemic of this disease, which prevailed to such a great extent last spring, and indeed which has prevailed so extensively in the past three or four years, has served to bring it prominently to the attention of all of us. It consists of an inflammatory process, involving one or both tonsils, which is characterized by the exudation into the crypts of the glands of a fibrinous material which fills and distends their cavities. The onset of the attack is marked by a chill, followed by general febrile disturbance of a marked character. The skin becomes hot and flushed, there are headache, pains in the bones, loss of appetite, and all the evidences of a febrile movement far greater

[1] Medico-Chirurgical Transactions, vol. liii. London, 1870.
[2] Les Tumeurs Adénoïdes du pharynx nasal.

than can be accounted for by the amount of local inflammatory action.

In a paper, read at the meeting of the American Laryngological Association in May last, on "The Clinical Significance of Fibrinous Exudations,"[1] I took the ground that this disease is an essential fever with a local manifestation in the throat, something in the nature of one of the exanthemata. I think there is much ground for regarding this as the correct view. In the same paper I called attention to the fact that the same disease occurred frequently in the pharyngeal tonsil. In each case the onset and progress of the disease is characterized by the same symptoms, the only difference being in the locality of the eruption, and in the subjective symptoms with reference to pain in deglutition, etc.

Croupous tonsillitis.—During the prevalence of follicular tonsillitis we meet frequently with cases in which the attack is marked by the same group of local and constitutional symptoms, with the exception that an inspection of the fauces reveals, in place of the small pearly white spots on the tonsil, a broad membrane covering more or less the whole face of the gland. This I regard as the same disease as the former, with an eruption which is more marked or efflorescent. The exudation which in the former case confines itself to the crypts of the glands, in the latter fills and overflows them, forming a continuous membrane. If this be detached from the surface, there will be found beneath it the appearances of the follicular disease.

The same membrane I have frequently observed on the pharyngeal tonsil, and its appearance is attended with the same general symptoms as in the faucial disease.

Diphtheritic tonsillitis.—A diphtheritic membrane on the faucial or pharyngeal tonsil occurs in connection with the blood-poison of diphtheria. Wherever it may be developed, its clinical significance is the same.

Hypertrophied tonsils.—Hypertrophy of the faucial tonsils gives rise to a train of symptoms which are mainly due to the mechanical presence of these glandular masses in the fauces. They occur mostly in young people. Their development is attended by the occurrence of repeated attacks of subacute inflammation or ordinary catarrhal sore throat, and they show a tendency to subside at puberty. Their development also is the result of a purely local morbid process, and is not, as a rule, the outcropping of any of the constitutional dyscrasiæ. If there is any impairment of health, it is to be accounted for by the mechanical action of the growths, in obstructing respiration, disturbing sleep, or otherwise interfering with the natural functions.

Hypertrophy of the pharyngeal tonsil has been described by many writers under the heading usually of adenoid tumors, or vegetations at the vault of the pharynx. It seems to me that a clearer comprehension of this affection would be reached by showing its relation with enlarged faucial tonsils. This form of hypertrophy, like that in the faucial tonsil, occurs mostly in young people: it gives rise to a train of symptoms which are largely mechanical; its development is attended by repeated attacks of subacute inflammation; it is a purely local trouble; it shows a tendency to subside with the attainment of puberty, and in fact in all its aspects is identical with the faucial disorder, except in its location.

In this view, then, enlarged tonsils in either region are simply masses of diseased glands, whose function has in the main been abolished or perverted by the morbid process which has fixed itself upon them. If the hypertrophic process is limited and the tonsils are of small size, giving rise to no untoward symptoms, either by their mechanical interference with function, or by exciting an abnormal discharge from the parts, they require no treatment. If, on the other hand, the hypertrophy has gone to the extent of developing a glandular mass, which by its presence interferes with the function of the parts, or which in any way gives rise to serious symptoms, it seems to me that there should be no question as to the proper remedy. They are diseased structures and should be extirpated. This rule, I think, should apply whether we have to deal with an exceptionally large mass, or with a single follicle not larger than a split pea. As regards any local medication I believe it to be absolutely inert in reducing genuinely hypertrophied glands. It is sometimes said that Nature placed these tonsils in the throat, and that they should not be removed. Nature certainly never put them there.

Perhaps one of the most remarkable suggestions ever made in regard to the tonsils was that of Penrose, that their removal might result in a loss of virile power. This strange suggestion has been so completely answered by Daly,[1] that I only allude to it as a curiosity. It is sometimes suggested that a portion of the tonsil might be removed, but not all. I see no more reason for this than for the removal of only a portion of any other morbid growth, a fibroid for instance. The danger of hemorrhage after tonsillotomy has often been urged as an objection to the procedure. This danger is, I believe, overestimated. Literature records no fatal case, as far as I know, with the exception of those cases in which the carotid artery was cut. I cannot conceive of an intelligent operator making this blunder. Furthermore, it should be stated, hemorrhage never occurs in the operation upon children. The nutrient artery of the tonsil in young people is small and its walls collapse easily. In adults, on the other hand, hemorrhage after tonsillotomy is almost the rule. This is often exceedingly troublesome. I have never seen a case, however, in which the bleeding was not promptly arrested by the application of a wire heated to a dull, red heat. This is a simple procedure and should be resorted to always in preference to the ordinary styptics, which are useless in controlling arterial hemorrhage, and the only troublesome bleeding which occurs in these cases is from the nutrient artery.

As regards the removal of the pharyngeal tonsil I have nothing to say in addition to what I have already given before the Academy[2] two years ago.

Quinsy.—I have already alluded to quinsy as a disease of the cellular tissue of the fauces rather than of the tonsil. Phlegmonous or suppurative disease does not occur in glandular structures, but belongs rather to areolar tissue. It is true that we occasionally meet with small abscesses in the glands of the tonsils or in other portions of the mucous membranes of the air-passages, but they are small abscesses, as a rule, which result from the occlusion of a gland, and are not phlegmonous in character. For three years I have entertained the view that quinsy was not a disease of the tonsil, and in that time have carefully watched and examined the cases which have come under my observation, and I do not recall a single instance in which I have not been able to demonstrate conclusively to my students, or others who have been present at my clinic, that the tonsil was not involved directly in the inflammatory process. The tonsil oftentimes presents a red and angry appearance, but this is always secondary, and due to the fact of its nearness to the phlegmon. Again, the tonsil is occasionally very prominent, being lifted from its bed, and at times projecting far toward the opposite side of the fauces. This is due to the phlegmon occurring behind it. The disease I believe to be an acute cellulitis of the areolar tissue of the fauces. In the very large majority of cases it occurs in the soft palate; in others it occurs in one or the other of the pillars of the fauces; and in still rarer instances, in the pharyngeal wall. Furthermore, the cause of quinsy I believe to be in very many cases the rheumatic habit. This view is an old one, and has been maintained by many writers on the subject. I had not paid any close attention to this view until Dr. Fowler[3] called renewed

[1] New York Medical Journal, May 12, 1884.

[1] Medical and Surgical Reporter, December 15, 1883.
[2] Growths in the Nasal Passages, MEDICAL RECORD, January 13, 1883.
[3] London Lancet, December 11, 1880.

attention to the connection between rheumatism and quinsy, and reported a number of cases which supported the view. Dr. Fowler also suggested the value of the salicylates in the treatment of the disease.

For three years I have treated all my cases of quinsy as cases of phlegmonous inflammation of the submucous cellular tissues, and as probably due to the rheumatic habit. The following summary is offered as affording some points of interest: The whole number of cases seen has been 133. Males, 88; females, 45. Under ten years, 3; ten to twenty years, 30; twenty to thirty years, 61; thirty to forty years, 11; over forty years, 12. The oldest case was sixty-nine years, the youngest nine months. This latter case was a female child which I saw the fourth day of the attack. The case had gone to suppuration and I opened the abscess in the soft palate.

In the 133 cases the phlegmon was in the soft palate in 115 cases; in one or the other of the posterior pillars of the fauces in 11 cases; beneath the tonsil in 2 cases, and in the wall of the pharynx in 2 cases. These latter two cases would have been called perhaps retro-pharyngeal abscesses. They were unquestionably quinsy. In many cases there was the clinical history of attacks of rheumatism, either arthritic or muscular. Unfortunately my notes give no accurate information as to the proportion of these cases, but I think it was fully sixty per cent.

If the effect of remedies is to be regarded as any evidence, the connection between the two diseases is still further evidenced by the fact that so large a number of cases of quinsy were aborted by the early administration of the salicylates. These cases were mostly seen at my clinic at the out-door department of Bellevue Hospital. Many of them came several days after the onset of the attack. Of those whom I saw within the first thirty-six hours, the attack was aborted by the administration of the salicylates in a majority of cases. In those cases in which the attack was not aborted, suppuration seemed to be very much hastened. The form in which the remedy was administered was as follows:

℞. Sodæ salicylatis..... ʒ iij.
Aquæ..... ʒ vj.
M. Sig.—One tablespoonful every two hours.

Last spring Dr. Barker suggested to me the value of bicarbonate of soda locally applied. The soda is to be taken up on the moistened finger and plastered over the inflamed surface every ten or fifteen minutes. I have since then made use of this remedy in connection with the salicylates, and in one or two cases its action has been most gratifying. I am not prepared, however, to abandon the use of salicylates in favor of the soda. In several cases also in which the quinsy habit has existed I have given the above prescription, with directions to commence its use immediately upon experiencing any symptoms of these attacks. These were cases in private practice. In no one of these cases has there been an attack of the disease. If the attack is not aborted by medication, it seems to me that it is of importance to us to recognize and treat the disease, as far as the local process is concerned, as an abscess in any other portion of the body. In other words, to treat it on general surgical principles. I think that the importance of introducing the finger into the fauces is not sufficiently recognized. No case—no case of quinsy, certainly—should ever be treated without it. By introducing the finger into the fauces, the condition and location of the phlegmon can be determined, and the occurrence of suppuration and the proper point at which to introduce a bistoury recognized. In this manner the treatment of a quinsy becomes a very simple matter, and does away with the use of gargles, inhalations, sprays, fomentations, etc., which oftentimes add to the discomfort of the patient rather than to his relief.

In conclusion, I have only to say that if I have brought forward any suggestions which are at variance with old established teaching, they are offered very modestly, but still as convictions which have been the result of a somewhat large experience. In acting upon them I am confident that I have obtained better results in the treatment of throat diseases than in following the older doctors.

TWO CASES OF NEURECTOMY FOR THE RELIEF OF FACIAL NEURALGIA.

By GEORGE R. FOWLER, M.D.,
SURGEON TO ST. MARY'S GENERAL HOSPITAL, BROOKLYN, N. Y.

The two following cases are deemed by me of sufficient importance to warrant their publication, inasmuch as they illustrate the two most common forms of neuralgia of the face and the complete relief afforded, in otherwise most intractable cases, by the resources of operative surgical art.

Case I.—Mrs. M. L—— applied to me in January, 1883, for the relief of a most violent and prolonged neuralgia, referred to the area of distribution of the frontal division of the ophthalmic or first portion of the fifth nerve. She had suffered more or less for several years with milder attacks in the same region, but the present attack had proven so severe and persistent, despite every therapeutical measure, that in sheer desperation she consented to submit to any plan of treatment which held out the slightest hope of relief. When she came under my care she had not had the slightest remission of the pain for full three weeks. Even opiates, unless pushed to the point of dangerous narcosis, failed to mitigate the pain. The conjunctiva upon the affected side was injected, ptosis was marked, and the lachrymal secretion flowed copiously upon attempts being made to raise the eyelid. There was intense tenderness over the point of emergence of the supra-orbital nerve from the foramen.

On February 4, 1884, I operated by Lienhart's method as follows: An incision was made along the upper margin of the left orbit, and in a direction parallel to the same directly down to the bone. The tarsal cartilage was separated upon a director. The supra-orbital nerve now came into sight, and by keeping the levator palpebrar, as well as the other contents of the orbit wall, depressed by a spatula, was traced back to the point where both it and the supra-trochlear branch are given off from the frontal nerve; beyond which point, after separating the trunk from its accompanying artery, it was severed. By means of a pair of stout scissors the fibrous bridge which binds down the nerve as it approaches the foramen was broken down, the nerve drawn out, and by retracting the upper lip of the horizontal incision, branches of the nerve distributed to the forehead were traced and dissected out. The supra-trochlear branch was divided at the point where it comes upward toward the pulley of the superior oblique muscle. The wound was irrigated with Koch's solution (mercuric bichloride, 1 to 1,000), its edges approximated by horse-hair sutures, and a naphthalinated cotton dressing applied.

The after-history of this case is entirely uneventful. The wound pursued an aseptic course, occupying less than a week in healing, and the neuralgia disappeared at once. Up to the present time, six months after the operation, there has been no return of the trouble, and a cure may confidently be asserted as having been accomplished.

Case II.—A. V——, aged fifty-three, German. This patient applied to me in March, 1884, for relief. His neuralgia was of the variety known as *tic douloureux*, and was of three months' standing; for the last six weeks of this time he had been deprived almost entirely of sleep, suffering all the while the most intense and agonizing torture. He had been treated by a number of physicians, and all the usual remedies had been prescribed for him, without, however, affording him any relief. The pain extended through the branches of the second division of the fifth nerve, upon the left side; hyperæsthesia of the

whole surface of affected area existed, as well as a most exquisite sensitiveness of the gum and teeth of the upper jaw of that side. The slightest touch of the integument or an attempt at taking food brought on a paroxysm of increased pain, with twitching of the left facial muscles. The pain was more or less constant during the intervals of freedom from twitching, but when the pain and "tic" were conjoined the agony was painful to witness.

On March 20, 1884, I performed the following modification of the operation first devised and practised by Carnochan, of New York: Ether having been administered, a curvilinear incision was made parallel to and slightly below the inferior orbital margin, from the inner to the outer angle of the eye. This was carried directly down to the bone and the flap dissected upward until the edge of the infra-orbital ridge was reached. The leash of nerves constituting the branches of the infra-orbital after it leaves the foramen was now dissected from the under surface of this flap. The tissues covering the anterior surface of the superior maxillary bone were next detached and drawn downward by a retractor and there held by an assistant. A trephine five-eighths of an inch in diameter was now applied in such a way that its point punctured the antrum of Highmore upon a vertical line running directly downward from the infra-orbital foramen, while its rim or cutting edge slightly overlapped the foramen itself. By following this rule in the application of the trephine, it was found that all of the available space possible was gained for operating. The removal of a button of bone from the anterior wall of the antrum having been accomplished, the patient was lifted from the operating table to a chair and placed in a sitting position with his back to a window; a reflecting mirror upon my forehead furnished the necessary light for the performance of the rest of the operation. The posterior wall of the antrum was now perforated by a trephine half an inch in diameter. In using this latter the centre-pin was withdrawn prior to its application, the converging surfaces of the cavity being found sufficient to support the instrument, and the danger of unwittingly thrusting the pin into the spheno-maxillary fossa avoided.

Upon perforating the posterior wall of the antrum, the spheno-maxillary fossa, together with its contents, was brought into view. With a small chisel the infra-orbital canal was opened and broken down so as to release the nerve and its accompanying artery, and tracing the nerve rapidly back to the point where it enters the orbit, with a pair of small double-curved scissors section of the trunk of the superior maxillary nerve was made beyond the point where it joins the ganglion of Meckel. The orbital, spheno-palatine, and inferior dental branches being divided, the ganglion and nerve-trunk were together drawn out. A smart hemorrhage from that portion of the internal maxillary artery contained in the spheno-maxillary fossa now occurred, but it was readily controlled by a small piece of compressed sponge attached to a stout thread and crowded into the fossa. This latter was left in position in order to guard against the bleeding. The parts were irrigated with Koch's solution, the external wound drawn together by a few horse-hair sutures, an opening being left at the most dependent angle for drainage, as well as to facilitate the withdrawal of the compressed sponge, and a dressing of naphthalinated cotton applied.

The next day the sponge was removed. Daily irrigations with Koch's solution and dressing with naphthalinated cotton were practised. The wound healed slowly, owing to the impracticability of keeping it in an aseptic condition, and a month elapsed before it had entirely closed. For the first few hours after the operation the patient complained of wandering pains over the whole left side of the face, but the "tic" had disappeared entirely, and in twenty-four hours he expressed himself as being perfectly free from pain; this improvement continued, and no recurrence of the pain took place. A slight depression exists at the site of removal of the button of bone.

Remarks.—Fortunately, as a matter of clinical experience, intractable and persistent facial neuralgia requiring operative measures for its relief is comparatively rare. It is a matter of congratulation, likewise, that it occurs, in the vast majority of cases, in nerves purely sensory, admitting of neurotomy or neurectomy without destruction of important functions. There can be no question as to the propriety of operating in these desperate cases, for a sufficiently large number are on record in which relief has been afforded to attest the value of the proceeding. In the choice of operation preference should always be given to neurectomy rather than to neurotomy, for the reason that experience proves that almost invariably the pain returns after the latter procedure, and even in some instances has been aggravated after a lapse of time, owing probably to the nerve becoming involved in the cicatrix at the site of operation. On the other hand, neurectomy gives a relief more or less decided and lasting.

As to the origin of these severe forms of neuralgia of the facial nerves, I can offer but little; nor can it be said that a positive opinion can be advanced in a given case as to whether the neuralgia is of central or peripheral origin. Fortunately, however, either variety is benefited, though not equally so, by neurectomy. In the central variety, there can be no doubt that the paroxysms of severe pain are induced by the application of stimuli to the periphery, and that a removal of the nerve-trunk and its branches as far as practicable destroys the medium by means of which these stimuli are conducted centripetally. The suspension of the excitability of the nerve-centre, even though temporarily, is of benefit by fulfilling the first indication in the treatment, namely, rest and freedom from irritation. Further, the reflected or irradiated pains, of themselves sources of much suffering, are relieved by quieting the central excitability.

Where the neuralgia is indubitably of peripheral origin, as for instance in those cases where a portion of a nerve-trunk or its branches are involved in a cicatrix, or a neuroma has developed upon the same, a cure may be confidently promised if neurectomy be resorted to. Here removal of the nerve-trunk as far away from the original point of irritation as is practicable is advised. Every effort should be made to promote rapid healing after operation, for the reason that the greater the amount of connective-tissue proliferation and formation of cicatricial tissue about the nerve-stump, the greater the chance of the developing therein of nerve-fibres, these communicating with or springing from the nerve-stump, and subsequently dragging upon the latter and becoming a renewed source of irritation. The antiseptic method of operating is, therefore, to be commended as being most likely to accomplish the best possible results.

Physio-Medicalism.—A correspondent asks for information regarding "physio-medical" colleges and practitioners. So far as we can learn, physio medicalism is an "ism" which flourishes only in Ohio and Indiana. There have been in Cincinnati a Physio-Medical College and a Physio-Eclectic Medical College, both of which institutions, like the good, died young. There is now in Cincinnati The Physio-Medical Institute, which has been in existence since 1877, and which graduates a dozen students every year. Its catalogue requirements are as high as those of most regular colleges, but it graduates a higher per cent. of students upon matriculants than the average. There is also a Physio-Medical College in Indianapolis, Ind., which was also founded in 1877, and which also graduates a very high per cent. of students. What the peculiar tenets of physio-medicalism are we do not know. There cannot be many over a hundred legitimate graduates in this specialty, and its existence is of small importance. The extinct institutions were probably merely advertising dodges for a few quacks.

LAPAROMYOMOTOMY.

Report of Two Cases Successfully Treated in a General Hospital.

By LEWIS A. STIMSON, M.D.,

PROFESSOR OF CLINICAL SURGERY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK.

I OFFER the following brief history of two cases of successful removal of the uterus and ovaries by abdominal section as a contribution to a subject which is now receiving much attention. A point of special interest is the fact that both were treated in the common ward of a general hospital. Each was a case of multiple fibromata of the uterus.

The antiseptic precautions consisted in thorough disinfection by the bichloride of mercury of the hands of the surgeons, of all sponges and cloths, and of the wound of the abdominal parieties by irrigation. The instruments were kept in a strong solution of carbolic acid, and the sponges that were introduced into the abdominal cavity were first purified by immersion in the bichloride solution and kept during the operation in a hot solution of carbolic acid. The pedicle was secured by transfixion and ligation with india-rubber cord, and treated by the extra-peritoneal method. The ligatures came away on the tenth and seventeenth days respectively. The external wound was kept covered with iodoform and dressings of borated cotton and iodoform or carbolized gauze. In each case the final cicatrization of the wound was slow.

In the first case, the stump of the uterus promptly sank back to its original position; in the second, it remained for several weeks drawn high up and firmly adherent to the anterior abdominal wall. At no time did the symptoms in either case cause more anxiety than that which would be naturally associated with the operation. In both cases I was greatly aided by the advice and assistance of my friend and colleague Professor Wm. M. Polk.

CASE I.—Effie V——, colored, about thirty years of age, was sent to me for treatment from Bedminster, N. J. I admitted her to the Presbyterian Hospital early in May, 1884.

She bore a child ten years ago. For the eighteen months preceding her admission to the hospital she had been troubled by an abdominal tumor, which caused much pain, entirely prevented her from working, and was accompanied by profuse menorrhagia. Her courses were very profuse.

There was a hard, irregular tumor within the abdominal cavity, extending from a little to the right of the median line in the hypogastrium upward and to the left to a point above the level of the umbilicus, and protruding into the vagina so as to force the uterus upward and backward almost beyond the reach of the finger. The tumor was slightly movable at first, and changed its position downward and to the right and became more movable while the patient was under observation. The cavity of the uterus was four and one-half inches long. The diagnosis was "pedunculated fibroid of the anterior wall of the uterus, with enlargement of the uterus by intra-mural fibroids."

May 24th.—Operation. The surface of the abdomen was washed with soap and water and then with the bichloride solution, the limbs and upper portion of the trunk wrapped in blankets, and the lower portion of the trunk wrapped in a rubber sheet in which an oval hole had been cut at the part corresponding to the field of operation. Over this sheet were placed cloths wet with the bichloride solution. An incision was made in the median line from a point a little below the umbilicus to the pubes, and all bleeding arrested before the peritoneum was divided. After division of the peritoneum the hand was introduced into the cavity, and with some difficulty the pedunculated tumor, which had a long pedicle, was turned out. The left ovary was found to lie at some distance from the uterus, and a double silk ligature was passed through the broad ligament below the pampiniform plexus by means of an ivory pin, and tied on each side of the ovary; the latter was then cut off. The right ovary lay close against the uterus, and as it was thought it could not be separately removed without risk of hemorrhage, and as the uterus was found to be studded with tumors, the latter was drawn forcibly upward, and its neck, which was long and free, was transfixed from before backward with the ivory pin, and a double india-rubber cord four millimetres in diameter drawn through and tied around each half. On the left side the rubber ligature passed just below the ligature that had been placed under the ovary; on the right side it passed outside the ovary and embraced the entire thickness of the broad ligament. Each ligature was drawn very tight and secured by tying it in a single knot and fastening the ends together close to the knot by a loop of silk. The uterus was then cut off and the stump brought to the lower angle of the abdominal wound and transfixed with two long pins close to the ligatures in the distal side. Very little bleeding took place from the punctures made in transfixion, and a sponge passed into Douglas' cul-de-sac brought out only a small clot of blood.

The peritoneum, the aponeurotic-muscular layer, and the skin were each united with a continuous catgut suture, and three silver wire and button sutures, not including the entire thickness of the wall, applied to bear the strain. A decalcified bone drain was placed in the parietal wound between the skin and peritoneum, extending from the upper angle of the wound to the stump. Iodoform, gauze, body-bandage.

The pedunculated tumor was flattened, and its pedicle ran from the centre of the flattened surface; it measured four by six inches across the top, and three inches from the pedicle to the upper surface; the pedicle was two inches long, one and a half inch wide, and one-fourth inch thick when compressed between the fingers. The uterus was irregular in form, with one small (one inch) pedunculated fibroid and many intra-mural ones; it measured four inches across the fundus, and the length of the portion removed was the same.

May 25th.—Temperature, 100⅘°. Slight abdominal pain. Ordered morphine, and an ice-water coil on each side of the abdomen. The wound had oozed freely, but was then dry. In order to make the application of the ice-water coil more efficient, the gauze dressings were removed, and a compress kept wet with the bichloride solution substituted.

May 26th.—Temperature, 100¼°.

May 27th.—Removed drainage-tube and button sutures.

May 29th.—Temperature, 98⅘°. Discontinued coil.

June 2d.—Removed the rubber ligatures, which were lying loose, and the slough of the stump. This left a good-sized suppurating cavity, at the bottom of which was an opening into which a probe passed easily to the depth of two inches below the surface of the skin. It was apparently formed by the sinking of the stump after it had become adherent to the peritoneum lining of the anterior abdominal wall. Dressed the wound with iodoform and dry absorbent cotton, the latter to be frequently changed.

June 9th.—The cavity is slowly filling, but the pouch at the bottom remains unchanged, except that its orifice is smaller; it is about one inch deep and one-third inch in diameter.

June 16th.—Wound is slowly contracting; pouch still one inch deep.

June 23d.—Pouch no longer recognizable; wound nearly flat.

July 1st.—Patient sits up; the neck of the uterus can be readily felt high in the vagina.

July 12th.—Wound entirely healed. Discharged.

CASE II.—Mrs. F——, forty years of age, entered the Presbyterian Hospital June 17, 1884. She had been suffering for eight and a half months with a tumor in the

lower part of the abdomen, profuse menorrhagia, and pain. For four months of this time she had continuous pain and fever, and she still suffers so much that, although fully aware of the risks of an operation, she desires to undergo it in the hope of relief. The tumor occupies the lower portion of the abdominal cavity, extending up to the umbilicus, is hard, irregular, and movable, and projects into the vagina, crowding the uterus so far back and upward that the os can barely be reached with the finger.

Diagnosis.—Intra-mural fibroids, probably with extensive adhesions.

July 8th.—Operation. This was conducted as in the preceding case. The uterus was found studded with intra-mural and sub-peritoneal fibroids, and the peritoneum covering it doubled by a soft, very vascular layer adherent to the rectum in bands. The right ovary was free and quite distant from the uterus; the left ovary was quite closely attached to the sigmoid flexure, and its tube was adherent to the rectum and sacral wall and dilated to one inch in diameter. The adhesions to the rectum were divided between double catgut ligatures, and the ovaries freed by transfixing and cutting between double silk ligatures. In the anterior wall of the uterus, low down, was a large globular fibroid, over the lower portion of which the bladder was broadly spread out. I made a transverse cut through the peritoneum above the reflection of the bladder, stripped the latter away from the uterus with the finger, passed a double rubber cord through the cervix and included fibroid tissue, and tied it. As it seemed inadequate properly to constrict the tissues embraced in its loop, I passed a second larger cord through the same puncture and tied with both, then cut away the bulk of the mass and enucleated from the stump the remaining fibroids and portions of fibroids. The parietal ligature beyond the left ovary meanwhile had slipped and some bleeding followed, which was arrested by passing an armed needle through the mass of divided vessels close to the sigmoid flexure and tying on both sides. The oozing in the pouch made by stripping up the bladder was quite free, and was finally arrested by the actual cautery; this pouch was drained by a rubber tube, its surface dusted with iodoform, and its mouth closed in great part by stitching the peritoneum together. The stump was brought to the lower portion of the wound and transfixed with four long pins. The peritoneal portion of the abdominal wound was closed by a continuous catgut suture, the musculo-aponeurotic layer by interrupted catgut sutures, and the skin by interrupted catgut and two silver sutures. A long decalcified bone drainage-tube was passed into Douglas' cul-de-sac, and the incision and stump dusted with iodoform and dressed with iodoform gauze, borated cotton, and a body-bandage. Morphine ordered.

July 9th.—Temperature rose gradually to 102° in the morning, and sank to 100⅘° in the afternoon. Changed dressing and removed the bone drainage-tube. The deeper layers of the dressing were saturated with a dark, thin discharge. Irrigation coil applied on each side.

July 10th.—Temperature, 100⅘°. Occasional pain, otherwise comfortable.

July 11th.—Much nausea; removed one inch of the rubber drainage-tube; dressing dry except for a small stain over the tube; temperature, 99° to 101°; morphine discontinued.

July 12th.—Temperature has remained below 100°; the only complaint is of the nausea and of pain caused by vomiting.

July 15th.—Changed dressing and removed the tube; temperature still below 100°; some little nausea.

July 16th.—Pressure caused about two ounces of pus to flow out beside the stump and from the upper angle of the wound.

July 24th.—Stump came away this morning; the ligatures had not cut through, but remained fast on the portion that sloughed off, the slough extending about a quarter of an inch beyond them. The cavity is an inch deep and its bottom flat and solid; the adjoining skin has turned inward, especially on the left side, and united with the surface of the wound.

July 26th.—After a severe fit of vomiting this morning free bleeding took place from the deeper part of the wound; it was arrested by lightly touching the bleeding point with the cautery.

August 14th.—The patient has been doing very well, except for occasional nausea. The wound is deeply retracted; the skin on the left side extends to the bottom; on the other side is a flat granulating surface about one and a half inch long and a quarter of an inch wide.

I failed to touch the cervix in vaginal examination. The abdominal wall at the wound is not movable upon the underlying parts; some tenderness on pressure on each side above the wound; told to sit up.

August 29th.—The wound has become level with the surface of the abdomen by the rising of the retracted skin, and is cicatrized at its centre. The cervix is lower and can now be readily felt in the vagina.

At intervals of about a week the patient has had attacks of nausea and pain in the lower part of the abdomen, which have always ceased after a free evacuation of the bowels has been obtained by enema.

September 11th.—Patient left hospital well and "feeling better than in years." There has been no recurrence of the nausea and pain in the abdomen since the latter part of August.

I chose the extra-peritoneal method of treating the pedicle because I deemed the consequent delay in the final healing of the external wound of no importance when compared with the security which the method gives against complications arising from retention of pus or decomposition of the portion of the pedicle embraced in the ligature. It may be that the first of these two cases would have done as well if the pedicle had been allowed to drop back into the abdominal cavity, but it could hardly have done any better. By the ninth day the ligatures had fallen, the abdominal cavity was closed, and there remained only the granulating wound of the anterior abdominal wall, and this soon cicatrized. With intra-peritoneal treatment of the pedicle the healing of the external wound may be equally delayed, and even when this healing takes place most promptly the patient gains but little in time or in security, for the risks or discomforts arising from the small unhealed surface are trifling, and a due regard for the safety of the internal cicatrices would compel an equally prolonged confinement to the bed even if the external wound were healed.

In the second case I am convinced that the intra-peritoneal method would have placed the patient's life in extreme peril. The cervix was itself occupied by tumors, and through two of these the ligature had to be passed. Separation took place, not in the plane constricted by the ligature, but at a little distance on its proximal side, apparently at the limit of the transfixed tumors, and when the ligatures came away (on the seventeenth day) they still firmly held the slough. It is extremely improbable that such an occurrence could have taken place within the abdominal cavity without provoking suppuration, and for the pus so formed there would have been no outlet except such as might have spontaneously formed. The formation and retention of that pus and the possible decomposition of the slough would have been most dangerous complications.

The only serious objection to the extra-peritoneal method which I foresaw was the possible interference of the pedicle with the subsequent distention of the bladder. I expected that the cervix would remain attached to the anterior abdominal wall closely enough to compress the bladder against the pubes and allow of its dilatation only on each side. This anticipation was not realized. In neither case did the patient find it difficult to retain her urine for the usual length of time, and in each the

cervix sank back (promptly in the first case, much later in the second) to its former place in the pelvis. Apparently this was accomplished by the stretching or sliding of the peritoneum after adhesion had taken place between its confronted surfaces; and in the first case, in which it was found to have occurred when the ligatures fell, a deep pouch like a glove-finger was formed and easily demonstrated at the bottom of the wound. The effect of this occurrence is to place the parts in what is practically the same condition as that in which they are left by the intra-peritoneal method of treating the stump, and thus to restrict the differences between the two methods to those existing during the process of repair of the wound. Those differences appear to make the extra-peritoneal method much the safer, for in it there is no possibility of the inclusion of a decomposing slough or of the retention of pus that has formed about the ligature, and if hemorrhage occurs through the slipping of the ligature, as has occasionally happened and with fatal results, it is at once detected and is accessible to treatment.

ANTISEPTIC MIDWIFERY.

By A. C. PAGE, M.D.,

TRURO, N. S.

MR. PRESIDENT: The object of this writing is to introduce the question of[1] "Antiseptic Midwifery," hoping in this way to obtain the experiences of wiser and abler men, so that while I am being taught, our younger brethren may catch some useful hints to help them over hard places. At the February meeting of the Colchester County Medical Association, Dr. I. W. McDonald, of Londonderry Iron Mines, was kind enough to give an object-lesson, illustrating the materials used and the manner of applying antiseptic dressings in surgery.

In the discussion that followed, Dr. Neil Sutherland, of Spring Hill Mines, called attention to the importance of antiseptics in midwifery practice, and Dr. McLeod, of Economy, related a case where, for want of such attention, he was caused great inconvenience and anxiety, he having, as he supposed, carried septic germs to his patient from a suppurating wound he had just previously been dressing, with nearly fatal consequences. I have been in the habit, from the beginning of my practice, twenty-eight years ago, of washing out the vagina with Labarraque's solution in all cases where the discharges after confinement were offensive, and my attention was called to it; but in many of my cases I never saw my patient more than once after delivery, and many not even once. Of late, however, the journals are teeming with articles on this subject, and the indolent or ignorant are being faithfully warned of the dangers by which our patients are surrounded constantly, and in a feeble way means are pointed out having for their end the avoidance of those dangers. Antiseptic midwifery, as well as surgery, is based upon the theory that the air we breathe, by which we are constantly encompassed, and which we cannot very well get away from, as well as the water we drink—that is, the few of us who drink water—in fact, our whole environment, is loaded with disease-germs, ready at all times—but sometimes with more malignancy than others—to pounce upon the unwary or unsulphurized, and enter by any or all avenues, particularly by raw or abraded surfaces, into the blood, and poison that precious fluid to destruction and death. The puerperal woman seems to have a peculiar attraction for these germs, and if one of them comes at all within her reach, it fastens itself with a death-grip upon the spot most favorable to the development of its destructive power, not only destroying her life, but multiplying itself till all persons and all things that have been near her are filled with the same deadly influence, which they may and do distribute, right and left, killing as they go. This is truly a fearful fact to contemplate, in the face of the other fact, that the only way known for obeying the scripture injunction, "Multiply and replenish the earth," is by woman assuming the risk of maternity.

One of the most talented and successful practitioners and teachers of female diseases, whose reputation is world-wide, and whom all who know honor and respect, recently published in one of the journals some "prophylactic measures which should be adopted in all midwifery cases, whether they occur in hospital or in private practice." Listen to them:

"1. The room in which the confinement is to take place should have the floor, walls, and furniture thoroughly washed with a ten-per-cent. solution of carbolic acid or mercuric bichloride, 1 to 1,000, and the bedstead and mattresses should be sponged with the same solution; carpets, curtains, and upholstered furniture should be dispensed with as far as possible.

"2. The nurse and physician should take care that all their clothing, both upper and under, be clean and free from exposure to the effluvia of any septic affection. Should either of them have been exposed within a fortnight to the effluvia of such affections as scarlet fever, typhus, erysipelas, septicæmia, or the like, they should change every article of clothing, and bathe the entire body, especially the hair and beard, with a reliable antiseptic solution; that which I prefer for this purpose is a saturated solution of boracic acid.

"3. As labor sets in, the nurse, having thoroughly washed her hands, cleaned her nails with a stiff nail-brush, and soaked them in antiseptic fluid, should administer to the patient a warm vaginal injection of antiseptic character; bathe the vulva and surrounding parts freely with the same; repeat this every four hours during labor, and keep a napkin wrung out of the warm antiseptic fluid over the genital organs until the birth of the child.

"4. Before the moment of labor both doctor and nurse should wash the hands thoroughly with soap and water, scrub the nails with a stiff nail-brush, and soak the hands for several minutes in a bichloride solution, 1 to 1,000.

"5. The third stage should be efficiently produced; all portions of placenta and membranes removed, and ergot administered in moderate doses three times a day, and kept up for at least a week, for a complete closure of the uterine cavity, expulsion of clots, and occlusion of the utero-placental vessels.

"6. The doctor, taking nothing for granted, should, at the conclusion of the labor, carefully examine the vulva of the patient. If the perineum be lacerated, it should be closed at once by suture, and should slight solutions of continuity be found in the labia or the vulvar extremity of the vagina, these should be dried by pressure of a linen cloth touched with equal parts of sol. ferri persulph. and carbolic acid, again dried thoroughly by pressure with the cloth, and then painted over with gutta-percha collodion. If this be thoroughly done absorption will be prevented at these points for at least three or four days, when the application may be repeated.

"7. After the labor, when the patient has rested, the vagina should be syringed out with an antiseptic solution, and a suppository of cocoa butter, containing from three to five grains of iodoform, should be placed within it under the os uteri. A syringe with intermittent jets should be used, which will wash away with gentle force all blood-clots.

"8. These vaginal injections and suppositories should, in cases of normal labor, be repeated every eight hours; in cases of difficult or instrumental labor twice as often, and these should be kept up for at least ten days, the nurse observing to the last the precaution already mentioned of washing her hands before every approach to the genital tract of the patient.

"9. When catheterization becomes necessary, it is safest to employ a new gum-elastic catheter, which before use should be thoroughly immersed in antiseptic fluid, and which should be destroyed at the conclusion of the case.

[1] Read before the Nova Scotia Medical Society.

"10. Last, but by no means least, let the physician inform himself by personal observation as to the competency of the nurse to syringe out the vagina, thoroughly to place the antiseptic suppositories just where they should be, and to use the catheter without injury to the patient."

These instructions were no doubt dictated by a kind heart, and are very well as far as they go; but it seems to me that in view of the prevalence of the cause of septicæmia, and the great necessity of protecting the lives of women, if it is only for the purpose of child-bearing, they fall far short of perfect protection. Perfect protection is, humanly speaking, impossible, I presume. No matter how clean the doctor and nurse may be when they start for their case, who knows what they may encounter and imbibe on the way? Sponging a bedstead and mattress is scarcely a practical suggestion for private practice, especially in the country. It appears plain enough that in this country especially, where there is such a feverish thirst for rapid increase of population, and in fact a political necessity for it, that the Government must take this matter in hand. The country should be divided into districts, and in each district should be built a large lying-in hospital, in a location approved by the Government sanitary engineer or commission. The buildings should be of iron and glass, with glass floors; the bedsteads of iron, japanned; the beds of rubber and air; carpets, curtains, and upholstered furniture should have no abiding-place in the buildings. The furniture of the lying-in room should consist of a bed and one or two white glazed earthenware basins *only*. All the rooms, when not in use, should be kept filled with the vapor of burning sulphur. There should be a sufficient number of suites of rooms, numbering from 1 to 16 in each suite, so that the patient could be promoted from No. 1, where she was delivered, to No. 16, advancing a room daily, by which time she might, under ordinary circumstances, be considered out of danger of septicæmia, and occupy the nursery parlors until she was fit to be returned to her family and friends.

Such a staff of doctors and nurses should be kept constantly ready that there would be no need of rushing from one case to another without sufficient time for antiseptic ablutions and thorough cleansing and rest. Every pregnant woman in the district should be compelled by law to report herself at the hospital at least two weeks before her expected confinement, for admission. She should be immediately scrubbed with some antiseptic fluid, and thoroughly new, clean, pure clothing provided for her. When her hour came she should be again thoroughly disinfected and conducted to the lying-in room No. 1, under spray. The doctor and nurse appointed to attend her should be thoroughly washed—not necessarily together—disinfected, and having been clothed in antiseptic gauze—not too thin—placed in a disinfected glass case and rolled into the room No. 1, with the patient, under spray, there to remain till the patient is delivered, washed, placed in a glass trough filled with warm disinfecting fluid, and passed under spray into No. 2, where another nurse takes charge of her and places her comfortably in bed. The doctor and nurse now retire from No. 1 as they entered, under spray, to their respective bath-rooms, and after being thoroughly scrubbed and clothed anew, they can await their next patient. In the meantime everything movable is taken out of No. 1, and the room thoroughly disinfected with burning sulphur, and made ready for patient No. 2. On the following morning patient No. 1, now in room No. 2, is gently and kindly washed, placed without clothing in the trough with antiseptic fluid, and rolled under spray into room No. 3, and put into a warm, clean bed. Room No. 2 is now cleaned, disinfected, and made ready for patient No. 2. The only persons having access to these rooms ordinarily are the doctors and nurses, and they invariably enter and retire under spray, as does any additional help required in cases of emergency.

All the details of nursing, feeding, and medical attendance are to be carried out with this single end in view, of avoiding the possibility of septic-poisoning, and under the strictest scrutiny of the Government sanitary engineer.

These details would be quite incomplete without taking proper precautions against the possibility of the mother being poisoned through fissures in her nipples from the infant's mouth. Millions of women probably die from poison absorbed in that way. Keep the child's mouth faithfully disinfected; but if a solution of bichloride of mercury is used for that purpose, it will be prudent not to make it too strong, for a strong solution of corrosive sublimate might prove prejudicial to the health of any but the very strongest of infants.

The deaths from puerperal fever amount to about one or two in a hundred in hospitals. The greatest mortality is in hospitals. In private practice, especially country practice, the mortality is less. In my own practice of twenty-eight years, and an experience of about a thousand cases, the mortality from septicæmia or puerperal fever has not been greater than one or two in a thousand, and it is a question whether, with such a record without any antiseptic precautions, it will be worth while to build such hospitals as I propose right away, or, furthermore, whether it would be prudent to surround the parturient woman with such meddlesome, wearisome watchfulness as will keep her constantly on the ragged edge of despair, and most certainly produce the very conditions we are most anxious to avoid. Death from puerperal fever is no worse, and scarcely more certain, than death from fear.

Don't allow anything I have written to lead you to suppose that I have anything but the most profound respect for science; but while I adore the teachings of science, I object to exciting unnecessary fears among a class of patients who at all times and under the most favorable circumstances have their nervous system severely taxed. More than half the lying-in women in Colchester County are attended by midwives, and among them puerperal fever is more rare than triplets. Take courage, therefore, my brothers, especially my younger brothers, and fearlessly, faithfully, and prayerfully if you like, do your duty to your puerperal patients, and I doubt not that He who hears the cry of the young ravens and tempers the winds to the shorn lamb will throw His strong arm and His disinfecting breath about the mothers of the future, as He so mercifully and consistently has in the past.

THE RIGHT OF PARENTS TO REFUSE SURGICAL AID FOR THEIR CHILDREN.—In a communication addressed to the *Raccoglitore Medico* Dr. Turazza, of Venice, raises the question as to how far parents should be allowed to interfere with the medical authorities in the treatment of their children. He cites some instances occurring in his hospital practice in which the lives of children were sacrificed because the parents would not consent to certain necessary surgical operations. And he asks whether, in the case of a sick or wounded child whose only hope of recovery rests upon the performance of some surgical measure, the parents should not be held guilty of homicide when they obstinately refuse to permit of the operation. And he also asks whether the surgeon, in such a case ought not, in hospital practice, at least where such a thing is possible, to undertake the necessary operation even in opposition to the will of the parents. These are certainly important questions, but at the same time questions upon which there is room for wide differences of opinion. Cases of this sort are not rare in which a life is seemingly sacrificed to the ignorant prejudices of parents, who cannot perhaps be blamed for refusing so sad an alternative. And yet the question of personal liberty is also involved, and it must be considered how far the State shall be allowed to encroach upon the family. Dr. Tarazzo did not himself attempt to answer the points raised but hoped to elicit a discussion and thereby to obtain the opinions of others.

Reports of Hospitals.

NEW YORK EYE AND EAR INFIRMARY.

Aural Service of SAMUEL SEXTON, M.D.

(Reported by William A. Bartlett, M.D., Assistant Surgeon.)

PAIN IN THE EARS DUE TO IRRITATION IN THE JAWS.

Some of the following cases of otalgia and inflammation of the ear were presented by Dr. Sexton to the physicians attending the aural clinical instruction given by the School of Ophthalmology, Otology, and Laryngology of the New York Eye and Ear Infirmary; others were taken from the clinical records. The experience of the clinic shows that among the poor earache is, in many instances, due to simple otalgia arising from dental caries. Sometimes it is found that even when otalgia is very severe indeed, no signs of hyperæmia or of inflammation are to be found in any part of the ear. Again, in certain chronic or acute inflammatory processes present in the ear, very great exasperation of the case is manifestly produced by the reflex agencies already alluded to.

These cases, divested of other details than those more particularly relating to the subject, are taken from the record-book in the order in which they presented themselves, and may be said to be fairly illustrative of the troubles under consideration. They do not, however, represent the entire number of cases of this kind seen during the period of time embraced between the first and last cases noted. Very often, it may be premised, a cure is effected in these cases by the extraction of diseased teeth.

Case I.—Bertha S——, aged six (vol. vii., p. 2). *Otalgia.*—Came to the Infirmary June 15, 1883. For the past year has at times had pains in ears, and two years ago one of them discharged. Several days ago pain began again in both ears, and she cannot sleep at night. *Examination* showed the left canal to contain a mass of cerumen; the right membrana tympani lustreless and hyperæmic. *Teeth:* Lower first and second molars on both sides mere shells. *Treatment:* She was recommended to have the shells extracted from the jaws, and was given small doses of the tincture of aconite root for the pains. *Remarks:* In this case the irritation from the carious teeth had doubtlessly been the cause of the collection of wax in the left canal and the otalgia in the right ear.

Case II.—Mary B——, aged twenty-one (vol. vii., p. 12). *Otalgia; Cerumen.*—Came to the Infirmary June 22, 1883. Complains of severe pains felt in left ear for two weeks, which seem to constantly get worse. Worse in open air, and at night so intense as to keep her awake. No tinnitus or discharge. *Examination:* Both canals filled with cerumen. *Teeth:* Both upper wisdom-teeth in a carious state. Both lower wisdom-teeth just cut. Owing to loss of some of the upper teeth, a vulcanite plate has been worn for four years past. *Remarks:* The irritation caused by dental caries and the cutting of the lower wisdom-teeth in the above case was increased, no doubt, by the vulcanite plate worn.

Case III.—Nora H——, aged forty (vol. vii., p. 44). *Otitis med. dif. Externa; Otalgia.*—Came to the Infirmary August 7, 1883. Has had headache for one year and a half, but never had aural trouble before. Has had pains in the right ear for the past two days without discharge. *Examination:* The teeth are exceedingly bad, and the right external auditory canal is the seat of diffuse inflammation. *Treatment:* Calc. sulphide in one-half-grain doses every three or four hours; tincture of aconite root in small doses.

August 10th.—Swelling less; feels a little better. The patient probably became more free of pain, for she did not return.

Case IV.—Henrietta G——, aged seven (vol. vii., p. 54). *Otalgia; Odontalgia.*—Came to the Infirmary August 14, 1883, with her own diagnosis—that her earache was due to toothache. *Examination:* The right membrana tympani is hyperæmic. *Teeth:* Both of the lower six-year molars are carious.

Case V.—N. M——, aged ten (vol. vii., p. 71). *Otalgia.*—Has had more or less deafness for five or six years past and teachers have occasionally discovered the defect in hearing. Was obliged to leave school on account of otalgia. *Examination:* The right membrana tympani lustreless, with prominent folds due to defective development. The left canal contains considerable soft wax, obscuring view of membrana tympani. *Teeth:* All of the six-year molars are carious as well as many of the other teeth. Hears a loud voice only in both ears. *Treatment:* Small doses of aconite were ordered and the teeth were to be attended to.

Case VI.—Amelia P——, aged twenty-two (vol. vii., p. 84). *Otalgia.*—Came to the Infirmary on September 18, 1883. Heretofore has never had any ear trouble, but for past two weeks has had a pain in left ear, intermittent in character, and worse at night when lying down. Had both upper canine teeth extracted and the upper right second molar, but this had no perceptible influence on the otalgia. The ear pain shoots over the brow and down the lower jaw. Has some laryngeal discomfort on account of pharyngitis with tendency to ozena. Menstruation is normal. *Examination:* Right canal small and membrana tympani hyperæmic. Canal contains small quantity of cerumen. The left ear in same condition as the right. *Teeth:* Had both upper second bicuspids removed previous to coming. In the lower jaw there remain in a carious state the two right inferior bicuspids and the first left bicuspid. Removal of the dead teeth recommended.

Case VII.—Lizzie C——, aged twenty, Irish, seamstress. *Otalgia.*—Came to the clinic October 1, 1883, giving the following history: No specific, malarial, or rheumatic taint. Has slight pharyngitis and has never suffered from dentalgia to any great extent. During the past four years has had repeated attacks of earache on left side lasting for a day or a day and a half, unaccompanied by tinnitus or deafness. The present attack, for which she came for relief, began four weeks ago and has continued constantly and quite severe to date. *Examination:* Teeth covered with tartar, several being carious in both the upper and the lower jaw. The auditory canals and tympanic membranes normal in appearance. *Treatment:* To have the dead teeth extracted and tartar removed. October 4th, removal was followed by almost complete relief. October 7th, has been entirely free from pains since last note was made.

Case VIII.—Mary L——, aged twenty-four (vol. vii., p. 119). *Otalgia; Otitis externa circ. Acuta; Disease of Teeth.*—Came to the Infirmary October 30, 1883. Takes cold easily. For a week so much pain in right ear that rest has been difficult, and in consequence she is very nervous. The right ear discharges a little; tinnitus is not complained of, and hearing is unaffected. Two years ago the ear pained without discharging. The teeth have ached a good deal. *Examination* of right ear showed that the meatus was closed by swollen tissues; hears a low voice in both ears. *Teeth:* Upper right first and second molars absent. Lower first right molar carious, and the third molar just cut. *Treatment:* Calc. sul., grs. $\frac{1}{10}$ every two hours; hot poultices.

November 3d.—No redness; pains ceased on night of the 1st inst., when a discharge began; canal contains some pus. Treatment continued. Advised to have dead teeth removed and fillings put into such as had sufficiently healthy pulps.

It is noteworthy in the above case, that besides dental caries there was the additional irritation caused by the rather late, and probably somewhat difficult, eruption of a wisdom-tooth on the same side with the affected ear, and it is not improbable that the previous otalgia experi-

enced was due to this cause. That the furuncle was due to the irritation in the nerves of the inferior maxillary branch seems most probable.

In commenting on this subject, Dr. Sexton drew attention to the frequent attendance of females suffering from aural trouble through sympathy of the nerves, and the comparative infrequency of the complaint among men; even in children, he thought the greater number of otalgias occurred among females. In reference to the treatment of these cases, it was believed that since dentistry had become such a popular business, and dead and diseased teeth had been so carefully retained in the jaws through their influence, especially among the better-to-do, nervous diseases about the head were becoming alarmingly common. The very general custom of wearing false teeth in the mouth attached to vulcanite rubber, celluloid, and other plates was also an evil of vast proportions. Indeed, he sometimes thought that the evil done through ill-advised dentistry was greater than the possible good arising from the work of the more capable dentists.

Progress of Medical Science.

The Dangers of Removal of the Thyroid Gland.—Dr. G. Zesas comes to the conclusion, based upon the results of a number of experiments on animals, that the thyroid gland is a supplementary organ to the spleen, and that its extirpation is followed by an increase in the number of the white blood-corpuscles. Death invariably ensued upon the removal of both organs. There is another much more important function of the thyroid gland, however, and this is its office of regulating the circulation within the cranium. As shown by Schiff, the removal of this gland is followed by nervous disturbances, such as stupor, sluggish movements without actual paralysis, fibrillary muscular contractions, and tremor, and even in some cases well-marked tetanus. Zesas concludes on this account that removal of the thyroid gland is a physiologically unjustifiable operation.—*Wiener Medizinische Wochenschrift*, August 16, 1884.

Masked Septicæmia.—Dr. E. Moritz relates three cases of septicæmia in which the symptoms were of an unusual character, leading at first to the diagnosis of some other condition. In the first case the patient complained chiefly of headache and pains in the limbs. The body was covered with numerous petechial spots. It was supposed at first, owing to the peculiar temperature curve, that the case was one of relapsing fever, but a daily examination of the blood failed to show the presence of spirilli. The diagnosis of septicæmia was then made and this was confirmed by the autopsy. The second case was supposed to be one of diphtheria, though the probability of septicæmia was recognized before death. In the third case the symptoms seemed to point to a commencing small-pox. In all these instances the autopsy revealed small sub-pleural ecchymoses, septic endocarditis, a large softened spleen, and parenchymatous degeneration of various organs. The points of infection seemed to have been: in the first case a large clavus on the sole of the foot; in the second a diphtheritic inflammation of the pharynx; and in the third case extensive submucous extravasations in the small intestine.—*Schmidt's Jahrbücher*, July 23, 1884.

Treatment of Strumous Adenitis by Nitrate of Silver.—Professor Ferraris recommends daily inunctions of strumous glands with an ointment containing one drachm of nitrate of silver to ten drachms of vaseline. Four applications usually suffice to obtain diminution of pain, or even complete resolution of the enlarged glands. It is claimed that by this means the inflammation is limited to the gland tissue, and the formation of fistulæ with subsequent cicatrices is averted.—*Journal de Médecine de Paris*, August 16, 1884.

Hydatid Cyst of the Liver—Spontaneous Cure.—Dr. Conti relates the case of a man, sixty years of age, of a robust physique, who had always enjoyed excellent health up to the time of his present trouble. He began to suffer from gastritis with violent pains over the hepatic region, like those caused by the passage of a biliary calculus. In a short time symptoms of hepatitis appeared, fever, jaundice, and enlargement of the liver without any signs of a distinct tumor. Finally the patient fell into a state of collapse, with constant vomiting and obstinate constipation. Some days later he had a number of diarrhœtic stools mixed with pus. On examination of the discharges an echinococcus cyst the size of an orange was discovered. The vomiting ceased, though the fever and diarrhœa persisted for some time, with symptoms of pyæmic infection. Dr. Conti believes the cyst was situated on the under surface of the liver and was discharged by ulceration through the wall of the colon.—*Journal de Médecine de Paris*, August 16, 1884.

Exsection of the Fascia in Dupuytren's Contraction.—In an article in the *Wiener Medizinische Wochenschrift* of August 9, 1884, Dr. R. Gersuny describes a new operative measure used by him in the treatment of contraction of the palmar fascia. He makes a longitudinal incision of the integument over the prominent aponeurotic bands, and then, through the opening caused by the retraction of the skin, excises this part of the palmar fascia. The wound is then easily closed by a few sutures and dressed antiseptically. The advantages of this method, he claims, are that there are no thickened and knotty cords left in the aponeurosis, and further, that owing to the direction of the line of incision in the skin there is but little retraction of the tissues and the wound heals readily.

Urinary Disturbances in Diseases of the Nervous System.—The urinary organs are often the seat of various troubles during the course of nervous diseases. In an article on this subject (*Revue Médicale*, August 23, 1884) Dr. Charles Féré groups these phenomena under disturbances of secretion, excretion, and sensibility. A diminution in the quantity of urine, he says, is observed, especially in severe forms of hysteria, when the ischuria may persist for several days. In such cases the vomited matters contain urea, a point of some value in the detection of malingerers. Under the influence of strong emotions there may be a decrease in the amount of urine passed, as well as a relatively smaller proportion of urea and chlorides. Polyuria may be caused by undue sexual excitement, severe neuralgia, and especially the milder forms of hysteria. Polyuria may also follow the renal or vesical crises of locomotor ataxia, and may exist as a permanent condition in affections of the mesocephalon. Albuminuria and glycosuria may accompany this condition, not only following lesions in the floor of the fourth ventricle but also occurring in diseases of the mesocephalon. A slight degree of albuminuria is met with also in several convulsive neuroses, and more particularly in epilepsy. The author explains this occurrence by supposing submucous extravasations into the walls of the bladder, similar to the facial ecchymoses sometimes occasioned by an epileptic attack. If the urine contains a large quantity of albumen, it is merely coincidental and due to some other pathological condition. A transitory neuropathic glycosuria may follow physical or mental fatigue, sexual excesses, or depressing emotions. The increase of urea and the urates may be encountered in any of the affections with clonic or tonic convulsions. Retention may be due to spasm of the sphincter or paralyses of the walls of the bladder. Paralytic retention is common in apoplectic coma, traumatic affections of the cord, Pott's disease, acute or subacute myelitis. In certain cases of this kind the urine becomes rapidly alkaline, a fact explainable only on the theory of some trophic trouble. True incontinence occurs only in

acute myelitis or in traumatic affections of the cord. Unconscious micturition is common in tabes dorsalis, general paralysis of the insane, and cerebral tumors located in the mesocephalon. The neurotic incontinence of childhood is often, the author asserts, a forerunner of epilepsy or ataxia. The various forms of irritable bladder may be met with in acute or chronic nervous conditions, in neurasthenia, spinal meningitis, or locomotor ataxia. The author does not agree with M. Geffier, who asserts that ataxia may be recognized by its urinary symptoms apart from any others, but he thinks that these troubles may often be of purely nervous origin, and are most probably of this nature in the absence of any well-defined lesions of the urinary tract.

Scrofula and Tuberculosis.—The history of the teachings upon tuberculosis and scrofula is a somewhat curious one. In the sixteenth century scrofula was the only condition recognized, but little by little tuberculosis began to assume an independent position in the minds of pathologists, and up to within a comparatively recent time they were supposed to be two separate and distinct diatheses or morbid conditions. But now tuberculosis began to get the upper hand, and one after another of the so-called scrofulous affections were recognized to be tubercular in character. Koch's discovery of the tubercle bacillus has lent additional weight to these views, and at the present day there are very few writers who would deny the tubercular nature of fungus arthritis, lupus, caseous cervical adenitis, and cold abscess. While some deny the very existence of scrofula as opposed to tuberculosis, others retain the name, using it merely to designate a diathesis or morbid predisposition. The exterior manifestations of this condition have been reduced to certain forms of eczema, impetigo, sluggish inflammation of the mucous membranes, and possbily superficial adenitis. But it is not certain that even these local manifestations of the scrofulous diathesis may not eventually be found to be caused by a mild form of tuberculosis. Dr. J. Grancher has recently inoculated guinea-pigs with pus and crusts of impetigo, and publishes the results obtained by him in *L'Union Médicale* of August 21, 1884. The experiments were all conducted with great care, every precaution being taken to protect the animals from contagion from without. Several inoculations were first made with pus taken from suppurating glands of the neck and from spina ventosa of the thumb, and in every instance the animals acquired tuberculosis. In the second series the pus was taken from impetigo crusts, strumous conjunctivitis, etc. The results were negative in all but two out of twenty-three cases. In the two successful inoculations the pus was not taken from the impetigo crusts, but in one case from a neighboring papule, and in the other from a small abscess of the skin. Dr. Grancher concludes that his experiments, as far as they go, would seem to show that the superficial scrofulous inflammations are not in themselves tuberculous, but that they may be the door through which the specific microbe gains admittance into the human organism.

Treatment of Suppurating Buboes.—This affection may be cured, according to Delahousse, in from six to twelve days by adopting the following procedure (*L'Union Médicale*, August 5, 1884): The skin is washed with soap and warm water, shaved, and then washed again with a one per cent. solution of carbolic acid. These precautions having been taken, the abscess is punctured and a solution of chloride of zinc (one part to six of distilled water) is injected into the cavity. After being retained for a short time in contact with the walls of the abscess, it is let out and replaced by a full injection of carbolized water. The wound is then covered with eight or ten folds of gauze saturated with carbolized water and glycerine (four per cent.). The dressing is retained for forty-eight hours, when the former procedure is repeated, the same precautions being observed.

Treatment of Dandruff.—M. Vidal uses the following pomade in the treatment of dry seborrhœa of the scalp (*Revue Médicale*, August 23, 1884): Precipitated sulphur, one-half ounce; balsam of Peru, one-half drachm; cocoa butter, three drachms; castor-oil, one and one-half ounce. The proportions of the cocoa butter and castor-oil should be varied according to the season to obtain a pomade of the desired consistency.

Acute Nicotinism.—In experiments upon dogs and rabbits Dr. Tomassio found that a subcutaneous injection of pure nicotine caused a reduction of temperature of from 1.5° to 2°. Immediately following the injection there was a slight muscular trembling, and a diminution in the number and force of the pulsations and respiratory movements. Collapse followed in from forty to fifty minutes. At the autopsy the author found congestion and hemorrhage into the lungs, the brain, and the abdominal organs. There was an intense odor of tobacco in all the tissues.—*Lyon Médical*, August 24, 1884.

Traumatism and Tuberculosis.—At a recent meeting of the Surgical Society of Paris (*L'Union Médicale*, August 5, 1884), M. Kirmisson related the case of a child, five and one-half years old, suffering from hemiplegia with contractures, coming on a week after a fall on the head. The appearance of the cerebral symptoms, severe pain in the temple on the side of the injury, the plaintive cries, vomiting, etc., led to the supposition of a purulent collection following probably a fracture of the cranium. Yet the slow progress of the symptoms, following at some interval the traumatism, caused M. Kirmisson to think that there might be a mere coincidence between the injury and the appearance of a tuberculous or cancerous neoplasm. The skull was nevertheless trephined, but with negative results, and the child died within twenty-four hours. At the autopsy the bones, membranes, and surface of the brain were found to be healthy. But in the centre of the right hemisphere there was a tuberculous mass which had destroyed the optic thalamus and corpus striatum. Histological examination established the tuberculous nature of the tumor. The speaker related several other cases, collected from the literature, showing a simple coincidence between traumatism and the development of tuberculosis.

Gastric Secretion in the Fœtus.—When iodide of potassium is given to pregnant rabbits it quickly appears in the amniotic fluid. It is often found also in the stomach of the fœtus, but this was supposed to be due to swallowing of the fluid, and, indeed, the fact was cited by Zuntz as a proof that the fœtus possessed the power of deglutition. Krukenberg, however, has found this substance in the stomach of the fœtus of the guinea-pig, after its subcutaneous injection into the mother, before it was present in the amniotic fluid. This would show that the iodide of potassium passed through the placenta into the fœtal circulation and was thence excreted (?) into the stomach.—*Wiener Medizinische Wochenschrift*, August 23, 1884.

Iodoform in the Treatment of Gonorrhœal Ophthalmia.—Dr. L. Guaita has treated successfully a severe case of blennorrhagic conjunctivitis on the following plan: Every morning, after having thoroughly bathed the eye with a solution of boracic acid, he filled the conjunctival cul-de-sacs with a quantity of finely pulverized iodoform. In addition, the eye was covered with iodoform gauze and a layer of gutta-percha cloth. This operation causes only a slight smarting, which disappears in a few minutes. If the iodoform gives rise to any severe pain it is because it is not finely enough pulverized.—*Journal de Médecine de Paris*, August 23, 1884.

Pelvic Hæmatocele.—In a thesis on this subject Dr. Jousset has collected the statistics of upward of thirty cases of pelvic hæmatocele, more than twenty of which ended fatally and were examined post-mortem. As a result of his studies he arrived at the following conclusions: 1. This affection is not a disease *sui generis*,

but is a symptom of several very different conditions. 2. The tumor itself is so characteristic that the diagnosis may be made without an exploratory puncture, provided only that the patient be seen early. 3. The symptoms of hæmatocele are for the most part those of the disease which has occasioned the extravasation. 4 One variety of hæmatocele arises in consequence of extra-uterine pregnancy or from rupture of the non-gravid condition. In this case the affection occurs suddenly with signs of internal hemorrhage, either after some vague symptoms of pregnancy or in the midst of perfect health. This manner of onset is rare and is of ominous significance. 5. Another form of hæmatocele, also rare and of evil prognosis, occurs in connection with uterine hemorrhage. It comes on rapidly after metrorrhagia, or more slowly after dysmenorrhœa. 6. The most common variety is that which arises in the course of pelvic peritonitis from rupture of the vessels in the pseudo-membrane. The prognosis in this form is of less gravity. 7. Surgical measures are only permissible when rupture into the abdominal cavity is threatened.—*Centralblatt für Gynäkologie*, August 23, 1884.

Hygiene of the Mouth in the New-Born.—In an article on the diseases of the mouth in infants (erythema, Bednar's aphthæ, stomatitis catarrhalis, thrush, etc.), Dr. Epstein states it as his belief that the most frequent cause of these affections is to be found in the manner of washing the mouth of the new-born child. The cleansing of the mouth, as usually performed by nurses and midwives, is done roughly and unskilfully, and not only causes injury to the mucous membrane, but is also frequently the means of introducing infection from without. He advises that the buccal cavity be washed only once a day after the morning bath, and protests especially against cleansing the mouth immediately after birth without previous disinfection of the nurse's hands. In the treatment of aphthæ no attempt should be made to remove any patches except those that lie within sight and easy reach, and any undue force should be most carefully avoided.—*Centralblatt für Gynäkologie*, August 23, 1884.

Symmetrical Brachydactylus.—Dr. K. Löbker relates the case of an otherwise normally developed woman who had a congenital shortening of four fingers due to absence of the middle phalanx. The thumb was, however, normal. The author argues that, in this case of symmetrical absence of the middle phalanx of all four fingers, if the first phalanx of the thumb were really the middle phalanx, it would also have been wanting. Hence the metacarpus pollicis cannot be regarded as a phalanx. —*Centralblatt für Chirurgie*, August 23, 1884.

The Weight of Drops.—M. Boymond has ascertained by a number of trials that the weight of a drop depends upon the external diameter of the tube, and not, as is usually supposed, upon its internal diameter. The size of the latter affects only the rapidity of the flow. The nature of the liquid (water, alcohol, ether, etc.) also determines the weight of the drop independently of any substances which it may hold in solution. In order to obtain drops of distilled water (of a temperature of 58.5° F.) weighing five centigrammes—or 80 drops to a drachm—the external diameter of the tube should be exactly $\frac{3}{5}$ inch. The author gives a table showing the comparative weights of drops of different medicinal preparations falling from a tube of the given size. One gramme (15 minims) of distilled water is equivalent to 20 drops; of alcohol at 90°, 61 drops; at 60°, 52 drops; of an essential oil, 48 drops; of a volatile oil, 50 drops; of laudanum, from 33 to 35 drops, varying according to its strength. The tinctures give a varying number of drops according to the proportion of alcohol. An aqueous solution, no matter what its strength, gives the same number of drops as distilled water. Thus two solutions of muriate of morphia of $\frac{1}{20}$ and $\frac{1}{100}$ respectively give each 20 drops to the gramme.—*Journal de Médecine de Paris*, August 23, 1884.

Periproctitis Simulating Typhoid Fever.—Professor Lücke relates the case of a strong and healthy man who was struck on the abdomen with a pole, but without receiving any apparent injury. Two weeks later he was seized with typhoid symptoms, high fever, and diarrhœa. These were followed by tenesmus, bloody, and then purulent discharges, a gangrenous piece of the rectum was passed, and soon the man died. At the autopsy there was found a perforation in the posterior wall of the rectum and a large fecal abscess extending to the sacrum. There were no typhoid lesions in the intestinal canal, no caries of the sacrum or coccyx, and no actinomycosis. The author believed that the affection was caused by a lodgment of the actinomycosis fungus in the folds of the rectum, giving rise to ulceration and abscess. The original fungus of actinomycosis can often not be found in abscesses of which it is the cause.—*Deutsche Medicinal-Zeitung*, August 21, 1884.

An Instrument for Pencilling Children's Throats.—Dr. H. Guttmann has devised an instrument to facilitate the making of local applications to the throat in dealing with refractory children. It consists simply of a wedge of hard rubber, with rounded edges, to the broad end of which is attached a handle. The wedge is perforated to permit the passage of the brush. By the use of this instrument it is claimed that the possibility of injury to the soft parts is done away with, the diphtheritic throat may be pencilled with great ease, and lastly the danger of infection from coughed-up matters is avoided.—*Deutsche Medicinal-Zeitung*, August 18, 1884

Acute Painful Paraplegia.—Dr. Dumolard describes under this name a special form of paraplegia, not mentioned in the books, of which he has had occasion recently to observe several instances. The affection commences with lumbar pain and a sensation of uneasiness and stiffness in the back. This pain, variable in its intensity and duration, begins in the lumbar region and extends up the back, passing sometimes into the neck. There may also be pains in the thighs and legs, not following, however, the course of the sciatic nerve nor localized in the joints, but extending over the entire surface of the limbs. When the patient attempts to walk, his gait is like that of a person suffering from rheumatism. In severe cases the pains begin with great intensity and are accompanied with a slight febrile movement. After some days of suffering the patient finds himself paralyzed in his lower limbs and is unable to rise from the bed. The reflexes are so exaggerated that the least touch on the feet excites tetanic contractions. The general condition of the patient is never serious, the pulse does not exceed 80, and the skin is moist. The bladder is usually somewhat weakened, but neither the paralysis of the bladder nor of the limbs is ever total. The pains are usually confined to the region of the kidneys and to the lower limbs during the whole course of the affection, but sometimes they leave these parts suddenly and attack the arms, which then also become paretic. The acute stage of the disease usually lasts from ten to fifteen days, the pain then rapidly subsides, and the paresis of the bladder and extremities begins to disappear. In all the cases observed by Dr. Dumolard complete recovery took place after from thirty to forty days. The cause of this affection is not determined, though cold and damp seem to have some share in its production. The persons attacked had arrived at the middle age. Counter-irritation along the vertebral column, purgatives, bromide of potassium, chloral, and morphine are the measures which seemed to do the most good in Dr. Dumolard's hands. The author does not regard the disease as belonging to any form of meningitis, but thinks it may be identical with an epidemic affection recently observed in Spain. This was characterized by pain and weakness in the lower extremities, and having once appeared in the village of Azannon recurred nearly every year under an epidemic form.—*L'Abeille Médicale*, August 25, 1884.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, October 4, 1884.

THE ALCOHOL QUESTION.

WHEN that goody young man Telemachus and his celestial guide Mentor, both models of excellent propriety for the times in which they lived, were on their memorable travels, they became acquainted with a race of people who probably had been educated from science text-books similar to those which are largely in use at the present day. "Do they drink wine?" Telemachus asks of Adoam. "Oh, no!" replies Adoam; "they would never do that! It is not because they want grapes—no country grows such delicious ones; but they content themselves with eating them before they are spoiled by fermentation, and they fear wine as the corruptor of man. It is a species of poison, they say, which maddens people; it does not kill a man outright, but it renders him a brute. Men can preserve their health and strength without wine; with wine they run the risk of ruining their health and losing their good manners."[1]

In discussing the alcohol question from a medical standpoint we have no occasion for denying that the ideal society which Fénélon describes was right in its judgment and in its practice, and that the Utopia of our civilization will be distinguished by temperance and sobriety. It is, however, notoriously a fact that society is not now, and will not for many years to come be, in that ideal condition; that debilitating diseases abound from whose results the remedial use of alcohol often offers the best means of defence; that multitudes of persons have weakly neurasthenic constitutions which seem to be benefited by the vinous stimulus indulged in moderation; that, in fact, alcoholic medication constitutes an important part of the physician's armamentarium: all this must be conceded, besides the uses of alcohol in the arts.

The two aspects of the subject must be kept in mind in any attempt to treat it fairly; the dark side with its horrors, which are undisputed (representing the abuses); the counterpart, or the strictly medical side, with which chiefly physicians are concerned and which has to do with the benefits obtainable from a physiological and therapeutical use of alcohol, which is properly a medicament, and as such of so great value that Raymond Lully styles it "the supreme cordial of the human body."[2] The discussion of the question is further complicated by the fact that the effects of alcoholic stimulants vary according to the *quality* of the spirit used and the *quantity* taken, and according as the individual is sick or well.

1. With regard to quality, this would have to be considered under several heads, such as the kind of alcoholic liquor used, whether fermented or distilled, and from what source, and whether modified by age and by the natural or artificial mixture of other substances, such, especially, as the higher atomic (amyl, butyl, propyl) alcohols. It is known that age has an improving effect on both fermented and distilled liquors, by some process as yet unknown. Eliminating such noxious impurities as fusel oil and aldehyde, in any case, whether used as a beverage or as medicine, the action of the intoxicant would be different on the economy according as the product ingested were fresh from the fermenting vat or still, or had become mellow from age.

That the natural or artificial contaminations of spirituous liquors, of which the most common and the most baneful is undoubtedly amyl alcohol, or fusel oil, materially modify the stimulant or narcotic effect of the alcoholic preparation is well known to physiologists at the present day. Of this we have lately had a decisive demonstration in the instructive experiments performed on animals (dogs and swine) by Drs. Dujardin-Beaumetz and Audigé, of Paris.[1] These experiments proved the exceeding noxiousness of all the higher atomic alcohols as compared with ethyl alcohol, as also the powerfully toxic nature of the alcoholic derivatives, acetic aldehyde, acetic ether, and acetone. This was shown by the results of acute poisoning with all these substances in the state of purity, and the state of dilution, and by the results of chronic poisoning which demonstrate the relative innocuousness of rectified wine, grain, beet, or potato spirits as contrasted with crude spirits that have not undergone rectification. A wide experience, moreover, has proved that the least noxious of the intoxicating beverages are those which approach the nearest to the matured products of vinous fermentation.

Organic chemistry has taught us that the alcohol which distinguishes vinous fermentation and vinous distillation is the ethylic—C_2H_6O. It has been again and again made clear that while a certain moderate quantity of diluted ethyl spirits may be borne by the human organism not only with impunity, but often with the happiest physiological results, the ingestion of even inconsiderable quantities of the other alcohols—unfortunately too generally components in notable proportion of the crude liquors of commerce—is attended with results which are always pathological and which are often most deplorable.

2. Under the head *quantity* we should have to consider acute and chronic poisoning by, and the stimulant and narcotic action of the alcohols. Here there is no dearth of facts from which to form judgments, and we now know the fixed toxic dose for every member of the alcohol series. It has been, for instance, shown that the medium quantity of ethyl alcohol sure to cause death within twenty-four hours is eight grammes per kilogramme of weight of the person or animal ingesting the spirit, and that the quantity of the other alcohols is much less; it has also been shown that when the daily dose of pure ethyl

[1] Fénélon's Télémaque, Liv. viii.

[2] Stillé: Therapeutics and Materia Medica: article, Alcohol.

[1] See these experiments detailed at length in the Therapeutic Gazette for July and August, 1884, with comments by Dr. Hurd, of Newburyport, Mass.

spirits does not exceed one gramme for each kilogramme of weight, it may be borne without inconvenience for a very long time, no perceptible lesions on the part of the digestive, hepatic, or nervous systems being produced.[1]

3. With regard to the action of alcohol on the human system, every physician is well aware of the difference of effect, whether the individual be in robust health or whether he be suffering from the debility of disease, quantities being toxic in the one case which are therapeutical and restorative in the other. There is no doubt that in sickness we often obtain a healthful stimulant action from doses which to a well man would be narcotic and detrimental; nor should there be any confusion between these terms stimulant and narcotic. The author of the best work in the English, if not in any language on stimulants and narcotics (Anstie), defines a stimulant as "any substance which, brought to bear in proper quantities upon the nervous system, facilitates nutrition." At the head of all stimulants he would place oxygen. Anstie's investigations show that alcohol is a food, medicine, or poison, according to the circumstances under which it is taken and according to the quantity taken. The effect of a small quantity he calls true stimulation, and urges that this is often beneficial, and comparable to the effect of food; a large dose produces narcotism, and is always injurious. A small stimulant dose is physiological, a large narcotic dose is pathological, and between the two there is a definite poison line, varying with each individual case. He denies that true stimulation is ever followed by reactive depression. True stimulation, whether produced by the oxygen we breathe or by the wine we drink, facilitates nutrition and hence supports life. Such, in brief, is Anstie's doctrine.

A careful consideration of the alcohol question from this standpoint and in the manner we have above indicated (which is the only fair way) shows how difficult and how complex is the problem with which legislators, sociologists, and educators are dealing; moreover, it will be seen how great are the difficulties in the way of a proper and comprehensive presentation of the subject in textbooks on physiology designed to instruct youthful minds in the truths concerning the actions of alcohol on the human system. Better that the children attending our public schools should grow up without this technical knowledge, but with the examples duly impressed upon them of the evils of intemperance on individuals, their families, and on society, all of which come under their daily observation and may be made by parent or teacher the theme of many an effective moral lesson, than that such loose and superficial teachings and half-truths as characterize the treatment of the subject by some of our physiological books should be instilled into their minds, much of it to be unlearned in after years.

DEAD TEETH IN THE JAWS.

THE columns of THE RECORD some months since contained several interesting communications to the effect that the retention of these defective members was not always unattended with danger to the patient. The "clinical notes on aural disease" in another part of THE RECORD furnish additional evidence of the perils of tooth-saving. It is stated by the careful observer that not only a large number of aural diseases, including otalgia pure and simple, may arise from the irritation of diseased teeth, but that doubtlessly a great deal of the nervousness with which some people are affected at the present day is attributable to the ill-advised retention of dead teeth and the unskilful stopping of teeth where the pulp is sensitive, though not as yet irreparably impaired by caries. It would seem, from the accumulated evidence on this point, that perhaps the time is nigh at hand when medical men should be themselves better informed concerning diseases of the jaws and mouth, rather than refer the ailments of this region to individuals whose limited knowledge of medicine does not prevent them from "treating" dead teeth long after their presence in the jaws has given rise to alveolar abscesses and neuralgias more or less painful.

One recalls in this connection the rather amusing emulation shown by the numerous correspondents of a London medical journal some years ago concerning the possibility of replacing teeth that had recently been lost, as though such a proceeding were one to be commended. It would not be strange if, in the course of events, the day would soon come when just the contrary practice would prevail—when all teeth without pulps, and hence in process of more or less rapid decay, as well as those which the deposit of tartar, or other cause, had entirely divested of periosteal nourishment, would be promptly condemned as unfit to remain in the jaws—regarded, in fact, as foreign bodies liable to give rise not only to cerebral irritation and disease in the organs of special sense, through the propagation of local disturbances in the mouth to the regions mentioned, but to endanger likewise the general health through purulent matter discharged into the mouth from alveolar abscesses, to be continuously swallowed for a long time, or, indeed, in some instances, to be absorbed and thus produce septicæmic poisoning.

It is certainly gratifying to note the establishment of instruction in oral surgery in some of the medical schools, and it is to be hoped that this subject will receive the attention its importance demands. It must not be supposed, however, that "dentistry" should be taught, for surely this in its broadest sense by no means constitutes oral surgery; nor does the latter embrace the former. The stopping of teeth and the fitting of plates in the mouth, requiring skill and experience for their successful performance, need no more be taught the medical student than the manufacture of surgical instruments and appliances. On the other hand, there has always been a desire to combine the medical art with the mechanics of dentistry, but the medical training usually given the dental apprentice is entirely too superficial to qualify him to treat disease, whether arising from the state of the teeth or not; in point of fact, his training does not always prevent harm being done to persons who are willing to have placed in the mouth some one or more of the numerous harmful dental appliances of the present day.

SOME THERAPEUTICAL DELUSIONS.

WE have received from an esteemed correspondent an extremely pungent criticism of the therapeutical fashions of the day. The writer earnestly urges the necessity of a more critical and careful analysis of therapeutical ex-

perience, and prays for a cyclone to strike some three-fourths of the therapeutical recommendations now in vogue. He concludes by enumerating a series of therapeutical delusions which he finds to be more or less current.

While we greatly deprecate nihilism in therapeutics, believing that that phase of medical feeling has had its day, we earnestly desire to encourage a more critical study of the action of remedies and of alleged therapeutic results.

We have carefully examined the "delusions" set forth by our correspondent, and find that in the main they agree with results of the more conservative clinicians and of pharmacological experiment.

They are as follows:

"It is a delusion that veratrum viride or aconite will abort croupous pneumonia or essentially modify its course; that potas. chlorate is of any use in catarrhal angina; that potassium nitrate is an antipyretic, anti-rheumatic, or (to any appreciable extent) diuretic; that lime-water will, in practice, dissolve a diphtheritic or croupous membrane; that nitrate of silver is of any value in epilepsy; that the excessive and continued use of iron induces plethora with dizziness, flushings, and palpitations; that iron should be given in phthisis; that mercury is antiplastic and antiphlogistic; that arsenic has any value in diabetes mellitus; that potassium iodide promotes absorption of serous exudations and non-specific connective tissue in hyperplasiæ; that sulphur and sulphur in baths is of any value in rheumatism; that charcoal, when moist in the stomach and intestines, has any absorptive power, or is of any use in flatulence by virtue of that power; that dilute acids are 'cooling,' *i.e.*, lower temperature and lessen heart-action in the non-febrile; that colchicum is of benefit in rheumatism; that drinking sulphuric acid prevents chronic lead-poisoning; that iodoform given internally is anything but a poor substitute for potassium iodide; that croton-chloral has a specific effect on the fifth cranial nerve; that tannic acid (or the plants containing it) is of any value given internally for hemorrhages, except perhaps those of the stomach and bowels, or that it is of any value as a gargle in chronic pharyngitis, or that it is an astringent to mucous surfaces and blood-vessels; that turpentine is a stimulant to the heart and nervous system; that musk is a nerve or heart stimulant (it belongs, with turpentine, to nerve depressants); that ox-gall is of the slightest therapeutical utility at either end of the digestive tract; that hydrocyanic acid in ordinary medicinal doses is either a local or general sedative (it is rather an irritant); that quinine in either small or large doses is a stomachic tonic, except in convalescence from malarial attacks; that hydriodic acid has any specific effects other than those possessed by the iodides."

PALATO-GRAPHY.

Dr. Harrison Allen, of Philadelphia, has described[1] a method of recording the movements of the soft palate, which is likely to prove of much scientific and perhaps practical importance. He says:

"When a straight rod is passed through the nose from before backward in the living subject, as far as is possible, it will be found to impinge against the roof of the naso-pharynx. In this position the rod is not influenced by any motions of the soft palate; but if the end of the rod which remains without the nostril be raised so that the rod be brought in contact with the anterior border of the nostril, the pharyngeal end of the rod will lie in a position which will cause a decided motion to be transmitted to it when the soft palate is raised."

By the use of a flexible copper wire attached to the rod, and then to a head-band, the rod is kept in place on the palate, and the free end is allowed to rest upon a revolving drum or kymographion, where it registers its movements. It is then found that the rod produces different curves with every motion of the palate in speaking, coughing, hawking, breathing, etc.

Dr. Allen has studied these curves and found them to vary for each of the different vowels and consonants, as well as for different words.

The tracings obtained are tolerably alike for the same words, although different individuals sometimes produce different tracings.

Dr. Allen gives illustrations of the tracings obtained with vowels, consonants, syllables, words, phrases, etc.

He believes that palato-graphy may be of use in studying the mechanism of the soft palate in disease, as well as in health. It may probably prove of use in studying stammering, and in determining the degree of degeneration of the levator-palati muscles in progressive dry aural catarrh.

It may also be employed in studying phonetics, and the suggestion is made that the instrument may be available for the comparative study of language, for the instruction of the deaf, and for the formation of a new system of short-hand writing.

While one can see many practical objections to such a rose-colored view of the future of the palate-myograph, it is evident that Dr. Allen has made an addition to our instruments of precision which will be of considerable value.

[1] A New Method of Recording the Motions of the Soft Palate. By Harrison Allen, M.D. Philadelphia: P. Blakiston, Son & Co. 1884.

News of the Week.

The Dosage of Phosphorus.—Dr. Rutgers, of Rotterdam, directs attention to a typographical error occurring in The Record of April 5, 1884, p. 376. It is there stated that Dr. Kassowitz recommends teaspoonful doses of a solution of phosphorus in cod-liver oil, 1 part to 1,000, in the treatment of rickets. The proportion should have been given as 1 to 10,000, the former dose being that suitable for an adult, and of course much too large for a young child. We always endeavor to be scrupulously exact in transcribing directions for the treatment of disease, especially when the question of the dosage of powerful drugs is involved, but errors will occasionally creep in, despite the greatest vigilance. It is always a good plan before accepting any formula, no matter by whom recommended nor where found, to make a simple calculation in order to determine the exact amount of the active ingredient contained in the prescribed dose. If this be done in every instance, errors of transcription or of printing can readily be detected, and the possibly unoward consequences averted.

Homœopathy and the Garfield Memorial Hospital.—In order to satisfy the demands of certain homœopaths at Washington, the Trustees of the Garfield Memorial Hospital have adopted the following by-law: "The executive committee shall provide that homœopathic treatment shall be furnished to those patients who desire it, provided the physician selected for such purpose shall render his services upon the same terms as the medical staff of the hospital."

Death of a Noted Epidemiologist.—The death is announced of Mr. John N. Radcliffe, M.R.C.S., one of the best of modern epidemiologists. He was the author of a number of painstaking reports upon epidemics, being especially skilful as a historian in that line. He was for some years one of the two public health inspectors of London.

The Cholera.—Up to September 30th, the total number of deaths from cholera in Europe was not far from 15,000. Of these Italy has over 8,000; France, about 6,000; Spain, 400.

In France there are now 23 Departments where cases have been reported, and 19 that have had deaths. The stricken communities number 237. Marseilles has had 1,733 deaths; Toulon, 982; Arles, 383; Perpignan, 186; Aix, 162; and Carcassonne, 106. The disease has nearly disappeared from France and Spain, and it continues to abate in Italy.

The total number of fresh cases in Italy, September 29th, was 355, with 212 deaths. This includes 171 cases and 100 deaths at Naples.

A cablegram from Paris, September 30th, states: "The cholera commission appointed to investigate the epidemic here have submitted their report. They state that they followed the progress of the disease by hourly examining the blood of persons stricken with it. They found that in each case at first a few of the globules presented an unhealthy appearance, then one-third were affected, then one-half, then two-thirds, and finally death resulted. The important fact was developed that all the globules were not simultaneously affected."

The American Academy of Medicine.—The Ninth Annual Meeting of the Academy will be held at the Johns Hopkins University, Baltimore, Md., on Tuesday and Wednesday, October 28th and 29th, beginning on Tuesday, at three o'clock P.M. The address of the President, Dr. Benjamin Lee, of Philadelphia, will be delivered at eight o'clock P.M. Papers will be read by Dr. N. Allen, of Lowell, Mass., on "Physiology in its more Public Relations (public health, physical culture, family institutions, true civilization)"; Dr. H. O. Marcy, of Boston, Mass., on "The Rôle of Bacteria in Infectious Diseases"; Dr. R. Stansbury Sutton, of Pittsburg, on "The Teachings Derived from Observations in One Hundred and Thirty-seven Abdominal Sections"; Dr. H. Knapp, of New York, on "Statistics of Glaucoma"; Dr. A. L. Gihon, U. S. Navy, on "The Trade Aspect of Medicine"; Dr. E. Jackson, of Philadelphia, on "The Examination of Applicants for Licence to Practice, a Means of Raising the Standard of Medical Education"; Dr. A. C. Kemper, of Cincinnati, O., on "Medical Fees"; Dr. V. P. Gibney, of New York, on "Some Comparative Results of Treatment of Chronic Articular Osteitis of the Hip"; Dr. C. C. Bombaugh, of Baltimore, Md., on "The Place of the Physician in Literature"; Dr. Peter D. Keyser, of Philadelphia, on "The Relation of the Medical Colleges to Preliminary Education"; Dr. A. D. Rockwell, of New York, on "The Induction Coil, its Varieties and the Differential Indications for their Use"; Drs. Dunglison and Marcy, "Report on Laws Regulating the Practice of Medicine in the United States and Canada."

The Comma-Bacillus found in the Mouth and Fauces of Healthy Persons.—Dr. T. R. Lewis, of the British Army, has been studying the microscopical appearances in cholera at Marseilles. He states that he finds the comma-bacillus in all cases, but that he has also found this bacillus in the mouth and fauces of healthy individuals. Although Dr. Lewis regards this fact as one of great significance, it cannot be so regarded as yet, since he did not test the oral microorganisms by cultivation.

Collective Investigation in Connecticut.—We have received a circular from the "Committee on Matters of Professional Interest in the State," in which is presented a plan for collective investigation among the members of the State Society. The subjects chosen for investigation are: convallaria maialis, piscidia erythrina, cascara sagrada, and the oleates. A list of questions under each head is furnished, and the members are each urged to do whatever is possible to promote the success of the investigation.

Dr. Alexander H. Stephens and Sir James Paget.—In an address delivered before the New York State Medical Society at Albany, in 1850, we believe, Dr. Alexander H. Stephens, President, gave a very similar series of facts and line of reasoning regarding the cost of sickness and disease that Sir James Paget did in his much-quoted address at the Healtheries. Dr. Stephens' address was not "much-quoted" however. Times were not then ripe.

The New York Post-Graduate Medical School and Hospital opened its Session of 1884–85 on October 1st, in its new and spacious building, where, during the summer, many changes have been made to add to the comfort of the physicians who attend the clinics. The building is four stories high, has a frontage of ninety feet, and has a large yard, in which is the well-ventilated building for the teaching of operative surgery, regional anatomy, and the like. In the basement is found the pharmacy and patients' waiting-room; on the first floor the amphitheatre, comfortable and light, for surgical, gynecological, ophthalmic, and other operations, and for the various clinics; also a second lecture-room for orthopedic surgery, and instruction in naval, military, and State hygiene; together with eight other rooms for the treatment of patients, and the reading-room, well supplied with medical journals. On the second floor is the large room for laryngoscopy, ophthalmoscopy, and otoscopy, with facilities for teaching thirty at once, if necessary. The new histological and pathological laboratory is also most thoroughly equipped, and contains one of the largest collections of specimens in this country. A photographic gallery for taking pictures of important cases is a new feature. The two upper floors are devoted to hospital purposes, where private patients are treated,

either in separate rooms or in a general ward, recently opened. Some of the private rooms are marvels of beauty. During the last session one hundred and eighteen physicians studied at the School, and the present demand for post-graduate instruction is on the increase. During the winter clinics will be given on the following topics: Surgery, Clinical and Operative; Gynecology; Venereal Diseases; Diseases of the Eye and Ear; Physical Diagnosis; General Medicine; Diseases of Children; Urinary Analysis; Surgical Dressings; Obstetrics; Applied Anatomy; Diseases of the Nervous System; Orthopedic Surgery; Diseases of the Nose and Throat; Skin Diseases; Pathology and Histology; Hygiene; Pharmacy; Anatomy and Physiology of the Nervous System; and Genito-urinary Diseases.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 21 to September 27, 1884.

MIDDLETON, PASSMORE, Major and Surgeon. Having reported from sick leave of absence, assigned to duty at Fort Leavenworth, Kan. S. O. 188, par. 2, Headquarters Department of Missouri, September 19, 1884.

WHITE, R. H., Captain and Assistant Surgeon. Assigned to duty as Post Surgeon at Fort Winfield Scott, Cal., relieving Assistant Surgeon A. S. Polhemus, who, upon being relieved will report to commanding officer Alcatraz Island, Cal., for duty. S. O. 113, par. 1, Headquarters Department of California, September 19, 1884.

HALL, JOHN D., Captain and Assistant Surgeon. Assigned to duty at Fort Townsend, Wash. Ter., to relieve Surgeon R. S. Vickery. Surgeon Vickery on being relieved directed to report to commanding officer Vancouver Barracks, Wash. Ter., for duty. S. O. 140, par. 3, Headquarters Department of Colorado, September 15, 1884.

TESSON, L. S., Captain and Assistant Surgeon. Directed to report to commanding officer Fort Stockton, Texas, for temporary duty. S. O. 127, par. 3, Headquarters Department of Texas, September 22, 1884.

BIRMINGHAM, H. P., First Lieutenant and Assistant Surgeon. Leave of absence extended twenty days. S. O. 116, par. 2, Headquarters Division of the Missouri, September 22, 1884.

MADDOX, T. J. C., First Lieutenant and Assistant Surgeon. Directed to report to commanding officer post of San Antonio, Texas, for duty. S. O. 127, par. 5, Headquarters Department of Texas, September 22, 1884.

BARROWS, C. C., First Lieutenant and Assistant Surgeon. Leave of absence extended one month. S. O. 97, par. 6, Headquarters Division of the Pacific, September 19, 1884.

DIETZ, W. D., First Lieutenant and Assistant Surgeon. Assigned to duty at Fort Selden, N. M. (Post Surgeon). S. O. 187, par. 4, Headquarters Department of Missouri, September 18, 1884.

MCCAW, W. D., First Lieutenant and Assistant Surgeon. Assigned to duty as Post Surgeon, Fort Craig, N. M. S. O. 187, par. 5, Headquarters Department of Missouri, September 18, 1884.

Official List of Changes in the Medical Corps of the U. S. Navy, during the week ending September 27, 1884.

BLOODGOOD, D., Medical Inspector. To Washington for examination preliminary to promotion, and as to qualifications for sea duty, October 1, 1884.

HORD, W. T., Medical Director. As member of Naval Examining Board, October 1, 1884.

TURNER, T. J., Medical Director. As member of Naval Examining Board, October 1, 1884.

BOYD, J. C., Passed Assistant Surgeon. Placed on waiting orders, September 25, 1884.

OBERLY, A. S., Surgeon. To Washington for examination preliminary to promotion, and as to qualifications for sea duty, October 1, 1884.

Reports of Societies.

AMERICAN GYNECOLOGICAL SOCIETY.

Ninth Annual Meeting, held in Chicago, September 30, October 1 and 2, 1884.

(By Telegraph to THE MEDICAL RECORD.)

TUESDAY, SEPTEMBER 30TH—FIRST DAY—MORNING SESSION.

THE Society was called to order by the President, DR. ALBERT H. SMITH, of Philadelphia.

DR. W. H. BYFORD, of Chicago, gave the address of welcome.

DR. JOHN C. REEVE, of Dayton, O., read a paper on

INVERSION OF THE UTERUS.

The following points wer among those upon which opinions were divided:

First.—Could inversion of the uterus occur entirely independent of pregnancy or polypus, or even in a nulliparous organ? There was a fair argument in favor of the proposition that it might so occur, and some cases seemed to prove it.

Second.—Did inversion of the uterus always begin at the fundus uteri? There seemed sufficient data to establish the proposition that inversion could begin at the cervix.

Third.—Did puerperal inversion of the uterus ever occur except at or immediately after delivery? Testimony rendered argument in its support unnecessary; several cases were mentioned which sustained the proposition.

Fourth.—Might inversions of the uterus take place without sufficient symptoms to attract attention or to indicate that anything had gone wrong? Cases were cited which sustained the affirmative of the proposition.

The paper was discussed by Drs. John Scott, of San Francisco; W. H. Byford, of Chicago; B. B. Browne, of Baltimore; A. Dunlap, of Sprinfigeld, O.; E. W. Sawyer, of Chicago; and W. T. Howard, of Baltimore.

DR. H. P. C. WILSON, of Baltimore, read a paper on

FOREIGN BODIES IN THE ABDOMEN AFTER LAPAROTOMY.

He had been unsuccessful in gathering statistics but had succeeded in collecting twenty-one cases. Of these only five had been published. Six occurred in this country, fifteen in Europe. In six American cases sponges were left in five, and forceps in the remaining one. Dr. Wilson gave a history of his case, that of a woman five months in pregnancy, upon whom he performed ovariotomy. Abortion occurred eighteen days after the operation. A sponge remained in the abdominal cavity five months; it was then discharged piecemeal through the abdominal walls, and the patient recovered completely.

The paper was discussed by DR. THOMAS, of New York. He said he was in the habit of attaching long pieces of tape to each sponge to prevent its loss in the abdomen. He had never had an accident occur to himself except once in four or five hundred laparotomies, and then a piece of sponge was found post-mortem, only a few hours after operation.

DR. A. REEVES JACKSON, of Chicago, knew of three unpublished cases, two in which sponge, and one in which forceps had been left in the abdomen. To pre-

vent accident he used a list of instruments and sponges, and compared the count after operations.

Dr. John C. Reeve, of Dayton, O., mentioned that Wilson used antiseptic sponges.

Dr. Dunlap, of Springfield, O., used few instruments and sponges, and allowed no one to put the hand in the abdomen except himself. He made the incision large so as to allow inspection, and used large sponges.

The discussion was continued by Drs. Howard, of Baltimore; Engelmann, of St. Louis; Mundé, of New York; Baker, of Boston; and was closed by Dr. Wilson, who stated that, from discussion and from one case learned otherwise, he could add seven to those reported in his paper; making a total of twenty-eight.

Tuesday, September 20th—First Day—Afternoon Session.

The Society was called to order at three o'clock by the President.

Dr. C. D. Palmer, of Cincinnati, O., read a paper on

ABDOMINAL SECTION—ITS VALUE AND RANGE OF APPLICATION AS A MEANS OF DIAGNOSIS AND TREATMENT.

In no class of diseases were there greater difficulties in diagnosis to be encountered than in certain pelvic and abdominal affections of women. Great stress had been laid upon the value of tapping as a diagnostic means. Probably the middle ground of favor occupied by most gynecologists was the correct one. But had not the importance of tapping as a means of diagnosis been exaggerated? The advantages offered by the plan were mentioned, and then reference was made to the immense damage that indiscriminate tapping had done. Tapping should be omitted if a diagnosis could be established without it, or some other equally risky procedure. The author of the paper would not assume the extreme position against it, but from experience we were justified in contending that tapping, in a large proportion of cases, in which it had usually been practised, was unnecessary and superfluous; for diagnosis, exploratory section was the only means in our possession to accurately determine certain diseases and conditions of the pelvis and abdomen. After referring to the views of Tait, Bird, Atlee, Kœberle, Spencer Wells, C. C. Lee, and his own experience, Dr. Palmer gave the general proposition that abdominal section was not dangerous in most cases, in which it appears justifiable. That

THE RISK OF PURE ABDOMINAL SECTION FOR DIAGNOSIS, EXCEPT IN MALIGNANT DISEASES, IS LESS THAN MIGHT BE EXPECTED.

In a group of cases the mortality would be heavier than in completed operations. Tait well remarked that the surgeon should most carefully consider what he was about to do before he turned an exploratory incision into an incomplete operation. Generally speaking, in all seriously doubtful and obscure cases of abdominal and pelvic disease, after other methods of exploration had failed, and when there were severe and threatening symptoms with urgent indications for relief, the abdomen might, or should be, opened. The diseases in which it might be resorted to were: First, ovarian tumors; second, certain interstitial and extra-uterine fibroids; third, certain cases of acute and chronic peritonitis; fourth, intestinal obstruction; fifth, chronic pelvic abscess; sixth, extra-uterine pregnancy. These explorative incisions should be performed antiseptically.

Dr. Engelmann, of St. Louis, thought that exploratory section had been practised too little in this country as a means of diagnosis. He regarded it as far more safe, and certainly more satisfactory, than tapping.

Dr. Mundé, of New York, regarded exploratory incision, in the majority of cases, as rather a safe procedure. In pelvic abscess he would first aspirate, and, finding pus, make a free incision.

Dr. Wilson, of Baltimore, regarded every ovariotomy as an exploratory incision, because it was very rare that the operator knew when he cut into the abdomen exactly what he would find.

The discussion was continued by Drs. Maury, of Memphis; Jackson, of Chicago; Scott, of San Francisco; and closed by Dr. Palmer.

Dr. P. F. Mundé, of New York, read a paper entitled

CERVICAL FIBROIDS AS A CAUSE OF DYSTOCIA, AND THEIR REMOVAL BY VAGINAL ENUCLEATION.

The paper was accompanied by specimens. It contained comments concerning the frequency of the occurrence of cervical fibroids, being much less frequent than tumors situated in the body of the uterus. A *résumé* of the literature of the subject, and a history of the case under his own care was related, in which a tumor weighing three pounds was removed by enucleation from the anterior lip and a portion of the body of the uterus of a woman thirty-eight years old, the mother of seven children. The patient recovered, and when discharged from the hospital nothing but thickening of the anterior lip of the cervix remained.

The meeting then adjourned to Wednesday morning.

The following were the members present: Drs. Baker, of Boston; Browne, of Baltimore; Byford, of Chicago; Dunlap, of Springfield, O.; Engelmann, of St. Louis; Foster, of New York; Howard, of Baltimore; Jackson, of Chicago; Jenks, of Detroit; Maury, of Memphis; Reeves, of Dayton, O.; Sawyer, of Chicago; Scott, of San Francisco; Smith, of Philadelphia; Vandewarker, of Syracuse; Wilson, of Baltimore; Johnson, of Washington; Mundé, of New York; Richardson, of Boston; Thomas, of New York.

Invited guests: Drs. E. C. Dudley, W. E. Clark, F. P. Seeley, N. S. Davis, of Chicago; P. McClure, of Dubuque; H. G. Dearborn, of Nashua, N. H.; J. H. Carstens, of Detroit; T. B. Harvey, of Indianapolis; Fritz Netzler, of Stockholm; F. Woodbury, of Philadelphia; and Wesley M. Carpenter, of New York.

A banquet was given by the Chicago Gynecological Society on Tuesday evening at the Palmer House.

Wednesday, October 1st—Second Day—Morning Session.

The Society was called to order by Dr. W. H. Byford, of Chicago.

The following gentlemen were made members by invitation: Drs. W. H. Meyers, Fort Wayne; J. H. Ranch, Springfield, O.; J. K. Bartlett, Milwaukee; Liston H. Montgomery, Chicago; T. A. Roger, Montreal; William Fox, Milwaukee.

DISCUSSION ON DR. MUNDÉ'S PAPER.

Dr. Jenks, of Detroit, reported a case in which a small cervical fibroid was present at labor, and which he enucleated without difficulty, and labor proceeded without interruption. He favored enucleation, although he was a believer in Cæsarean section if performed before the woman becomes exhausted.

Dr. Byford, of Chicago, said his practice had been, whatever was the size of the tumor, whether sessile or pedunculated, to wait until labor began, believing that these tumors can be removed as easily at that time as at any other. Thus the danger of producing miscarriage, and consequently sacrificing the child, was avoided; besides, in many of these cases the tumor was pushed before the head and delivery completed without injury to the child.

The discussion was continued by Drs. Wilson, of Baltimore; Dunlap, of Springfield, O.; Van De Warker, of Syracuse; Reamy, of Cincinnati; and closed by Dr. Mundé.

Dr. T. Gaillard Thomas, of New York, read a paper on

EXTRA-UTERINE PREGNANCY, WITH REPORT OF SIX CASES.

It was supplementary to a report made two years ago. Notwithstanding the great advance made concerning

early and certain diagnosis, it was far from easy. The dictum of Depaul, however, that diagnosis at third or fourth month was impossible, must be disregarded. Reference was made to experiments performed on rabbits by Leopold, who introduced fœtal rabbits after performing laparotomy and studied the changes which followed. They had a direct and favorable bearing on destruction of the fœtus by means of the galvanic current. Leopold also believed that recovery of patients after rupture of the Fallopian tube was much more common than generally supposed, a position which Dr. Thomas fully endorsed. Dr. Stephen Rogers, of New York, twenty years ago advocated laparotomy and application of ligatures for control of hemorrhage from rupture of blood-vessels with extra-uterine pregnancy, but had no experience in the plan of treatment. Lawson Tait, in January, 1883, operated under these circumstances, and in 1884 in four additional cases, with four recoveries in all. Dr. Charles K. Briddon, of New York, followed Tait, in October, 1883, and the history of the case was incorporated in his paper. Dr. Thomas' conclusion upon this point was that neglect to perform laparotomy under such circumstances would be criminal. The author of the paper then gave detailed histories of six additional cases of extra-uterine pregnancy treated with the galvanic current.

The paper was discussed by Drs. Mundé, of New York; Harvey, of Indianapolis; Palmer, of Cincinnati; Wilson, of Baltimore; Howard, of Baltimore; Baker, of Boston; and Reamy, of Cincinnati.

Dr. R. B. Maury, of Memphis, read a paper entitled

CASE OF TUBAL PREGNANCY WITH RUPTURE OF THE SAC AND REMARKS CONCERNING THE PROPRIETY OF LAPAROTOMY.

The case was one of ruptured perineum with rectocele cured by the usual operations, and followed by pregnancy in which there developed suddenly evidence of rupture of the sac of extra-uterine pregnancy, diagnosticated to be of the tubal variety. The patient recovered. After referring to the views of Tait, Thomas, and others, Dr. Maury submitted that even under perfect surgical methods, we may never hope, as a rule, to obtain satisfactory results from immediate laparotomy, and at this time it would seem to be more in accordance with sound surgical principles to postpone all consideration of laparotomy until the period of shock had passed away.

Wednesday, October 1st—Second Day—Afternoon Session.

The Society was called to order by Dr. Jackson, of Chicago.

Dr. Christian Fenger, of Chicago, was made a member by invitation.

Dr. P. F. Mundé read a paper entitled

LIMITS OF VAGINAL HYSTERECTOMY FOR CANCER.

It was essentially a rejoinder to a paper by Dr. Jackson, of Chicago, read at the meeting last year, in which the conclusions were reached, *first*, that a diagnosis of uterine cancer could not be made sufficiently early to insure its complete removal by extirpation of the uterus; *second* that when a diagnosis could be made there was no reasonable hope for a radical cure, and other methods of treatment for ameliorating suffering or retarding the progress of the disease, and prolonging life, were equally effectual; *third*, that extirpation of a cancerous uterus was a dangerous operation. The author reported two cases and exhibited specimens. He then discussed the propositions made by Jackson from a clinical and statistical point of view, and reached substantially the following conclusions concerning the precise conditions in which alone operation seems justifiable: *first*, absolute limitation of the cancerous disease to the uterus; *second*, the probability of a complete removal of the disease by high supravaginal amputation and cautery, questionable; *third*, cancer or sarcoma of the body of the uterus; *fourth*, perfect freedom of motion of the uterus; *fifth*, capacious vagina; *sixth*, sufficiently vigorous condition of the general system. What he wished to accomplish by the paper was to protest against wholesale condemnation of a perfectly radical surgical measure on the more or less theoretical ground that it is too dangerous and not sufficiently beneficial, when facts, as shown by statistics, prove to the contrary, and to claim for the operation certain justification.

Dr. Jackson, of Chicago, maintained that surgical procedure, to be justifiable, should alleviate suffering and prolong life. The operation under consideration did neither of these, and therefore was unjustifiable without regard to special cases.

Dr. Van De Warker, of Syracuse, said the question was not how many died and how many recovered after operation, but was there any better way to reach the same result? He believed there were other methods which were safer and equally as competent as the use of the knife.

Dr. Engelmann, of St. Louis, argued in favor of operation, and claimed that the success already obtained warranted its continuation until more fully tested.

Dr. Palmer, of Cincinnati, thought that vagnial hysterectomy was not applicable in cases in which cancer had its starting-point in the cervix.

Dr. Baker, of Boston, sustained the operation as justifiable.

Dr. Scott, of San Francisco, thought young fellows were arranged upon one side and old fellows upon the other.

Dr. Reamy, of Cincinnati, thought statistics did not prove, nor did the paper prove, that operation prolonged life or cured the disease, or from a clinical standard that it was justifiable.

The discussion was continued by Dr. Ferger, of Chicago, and closed by Dr. Mundé.

The Society then adjourned to Thursday morning.

Thursday, October 2d—Third Day—Morning Session.

The delivery of the President's address on the present aspect of the puerperal diseases was postponed on account of the sickness of the President.

Dr. Edward Sawyer, of Chicago, read a paper on "Occipito-posterior Position in Vertex Labors." A paper was also read on "Rare and Fatal Form of Sepsis without Symptoms," by Dr. G. J. Engelmann, of St. Louis.

PAPERS READ BY TITLE:

"Hygiene of Pregnancy," by Dr. S. C. Busey, of Washington; "Rapid Dilation of Cervical Canal," by Dr. William Goodell, of Philadelphia; "Physiognomy of Vulva a Sequence of Anal Disease," by Dr. Isaac E. Taylor, of New York; "Early History of the Treatment of Vesico-Vaginal Fistula in the United States," by Dr. Nathan Bozeman, of New York; "Periodical Symptoms in Uterine Disease," by Dr. G. J. Engelmann, of St. Louis; "Topography and Sectional Anatomy of the Female Pelvis," by D. B. Hart, of Edinburgh; "Fibro-Myomata of the Uterus," by Dr. R. S. Sutton, of Pittsburg.

The following officers were elected: *President*—William T. Howard, Baltimore, Md.; *Vice-Presidents*—W. L. Richardson, Boston, Mass., and Paul F. Mundé, New York; *Secretary*—Frank P. Foster, New York; *Treasurer*—Matthew D. Mann, Buffalo, N. Y.; *Members of Council*—A. Reeves Jackson, Chicago, Ill.; H. P. C. Wilson, Baltimore, Md.; Joseph Tabor Johnson, Washington, D. C.; Ely Van De Warker, Syracuse, N. Y.

The next meeting will take place at Washington, D. C., on the third Tuesday in September, 1885.

THE HOSPITALS MEDICAL SOCIETY OF PARIS.

Stated Meeting, July 25, 1884.

M. Bucquoy, President, in the Chair.

(Special Report for The Medical Record.)

The Society having been called to order by the President, M. Martineau rose to state his views upon the relations of

SYPHILIS AND CHOLERA,

and the influence exerted upon the latter by the former affection. It had been asserted that the mercury given in the treatment of syphilis, especially the biniodide of mercury, acted also as one of the best prophylactics against cholera. The speaker opposed this view, and stated that of nine fatal cases of cholera occurring during the epidemic of 1849 in the Hôpital de Lourcine, eight of the patients were under treatment for syphilis. A similar experience obtained in 1866. At that time two wards were devoted to the reception of cholera patients, but the disease spread throughout the hospital and attacked by preference the syphilitics.

M. Dujardin-Beaumetz had observed the same untoward results in the case of

SYPHILIS AND TYPHOID FEVER.

It had become a common saying in the Hôpital Cochin that a patient in the early stage of syphilis, if attacked by typhoid fever, was a doomed man. Thus the mercury was seen to fail likewise in this disease. It was true, as stated by Miquel, that the biniodide of mercury was a most powerful disinfectant. But it was very unsafe to reason that, because a certain drug acted as a microbicide in the test-tube, it would act similarly in the human organism.

M. Bucquoy agreed with the last speaker as to the gravity of typhoid fever when it attacked a patient already suffering from syphilis.

M. Damaschino recalled several fatal cases of cholera occurring in syphilitic patients during the epidemic of 1866.

M. Féréol regarded syphilis and cholera as a combination of great gravity, but could not entirely agree with the last speakers as regards the evil influence of syphilis upon the course of typhoid fever. He had seen a number of cases of this kind in which recovery took place.

M. Vallin exhibited a

CHAMBERLAND'S WATER FILTER

made after the model of that used by Pasteur in his laboratory. Two cylinders are placed one within the other, the inner one being made of porcelain and being the filter proper. A pressure of one atmosphere and a half was necessary to force the water through the sides of the cylinder. The water was cleared absolutely of all suspended matters. The filter could be readily taken apart and purified by passing the inner cylinder through a flame.

M. Gérin-Roze thought the objection to such a filter was that it removed the suspended particles, but not the matters held in solution. He preferred a charcoal filter, even though it might be a little more complicated and difficult to cleanse.

M. Dujardin-Beaumetz presented a young man in whom there was a

TRANSPOSITION OF THE VISCERA.

The patient had had a pleurisy with effusion, and the heart-sounds were heard on the right side. But after the pleurisy was cured the heart still remained on this side, and it was then that the fact of the transposition of the viscera was noted.

M. Bucquoy had observed a similar state of affairs in a woman. In this case the patient herself called attention to the fact that her liver was on the left side.

M. Damaschino presented a communication on the

DISTOMA HÆMATOBIUM

offered by a physician of Alexandria. The microscopical preparations which accompanied the paper were from cases of distoma of the liver and of the kidneys.

M. Dujardin-Beaumetz then read a paper on the

DIAGNOSIS OF CANCER OF THE STOMACH.

His object was to call attention especially to the difficulties of a correct diagnosis. There was indeed no certain pathognomonic symptom of carcinoma of the stomach. In the first place, we are usually unable to determine the exact nature of any internal tumor. Histology has given us a very complete list of the various forms of cancer, but clinically we can make no such fine distinctions.

It has been asserted that the duration of carcinoma is shorter than is that of other chronic affections of the stomach, three years being given as the maximum. But while this might be true of some varieties of cancer, it was not so of all. The author recalled one case of undoubted carcinoma, as proved by autopsy, in which the earliest symptoms preceded death by twelve years. It might be objected that the case was one of cancer following ulcer of the stomach, and that the earlier symptoms were those of the latter affection. Such an assumption was, however, gratuitous, and, besides, the author had seen other cases in which the duration, though shorter than in the instance just cited, yet exceeded greatly that usually set down for carcinoma.

The diagnosis between cancer and dilatation of the stomach was a matter of considerable difficulty. As regards sex, men are more subject to cancer, and so they are to dilatation. Both affections are met with usually at about the age of forty years. Quesnel's assertion, that every cachectic person suffering from a chronic affection of the stomach has carcinoma, cannot be maintained. And even painful œdema of the legs, regarded by Trousseau as characteristic of cancer, may occur with simple dilatation. Pain is not a symptom of any great value, for although it usually exists it may also be absent. The vomiting of coffee-ground matters, formerly regarded as pathognomonic of cancer, may occur in dilatation, and is therefore a sign of no exceeding value. Even the existence of a tumor may be misleading, for a thickening of the stomach walls may occur in dilatation and may be mistaken for cancer. If, however, the tumor be well defined and lobulated, the diagnosis of cancer is rendered fairly certain. The German method of setting free a large quantity of gas in the stomach, the author considered to be practically of no value in diagnosis. It has been asserted that in the case of cancer the hydrochloric acid is wanting in the gastric juice, but this is equally inapplicable and valueless in practice.

M. Romelare, of Brussels, had noted a fact which M. Dujardin-Beaumetz thought might prove useful in this connection. He had found that in cancerous affections of the stomach and liver the amount of urea excreted was reduced to an average of 120 grains, and never exceeded 150 grains in the twenty-four hours. In the case of ulcer of the stomach, on the other hand, the amount of urea ranged from 250 to 500 grains, and never fell below 225 grains per diem. The author had verified these conclusions in a general way, yet they were not entirely reliable as a means of diagnosis. He had had a patient in whom the daily amount of urea excreted was but 45 grains, and had therefore concluded that the disease was cancer, but found at the autopsy that the tumor was an hydatid cyst. There was still another procedure which might be of assistance in establishing a diagnosis. He had procured an amelioration, and even a temporary lull, in the symptoms by regular and methodical washing out of the stomach in the case of carcinoma. In the case of dilatation, however, no improvement was obtained by this practice.

Upon the conclusion of this paper the Society adjourned.

THE THERAPEUTICAL SOCIETY OF PARIS.

Stated Meeting, July 23, 1884.

M. DELPECH, PRESIDENT, IN THE CHAIR.

(Special Report for THE MEDICAL RECORD.)

WHEN the Society had been called to order there arose a short

DISCUSSION ON ANTISEPTICS.

M. DUJARDIN-BEAUMETZ thought that the toxic nature of any substance should be considered as well as its antiseptic powers. A drug might be a perfect microbicide, but might also be practically useless because of its strongly poisonous qualities. The best antiseptic was undoubtedly that which was the least harmful to man in the dose required for asepsis. He regarded boracic acid and borax as the best microbicides for internal use that we possessed, as they combined at the same time a high degree of antiseptic power with an almost complete absence of injurious properties to the human subject.

M. BRÉMOND spoke in glowing terms of

OZONE

as the best disinfectant of the air in sleeping apartments and other enclosed spaces. A sufficient quantity of this substance may be produced with great ease by using a spray of spirits of turpentine.

M. LIMOUSIN stated that by making a mixture of permanganate of potash and bisulphate of potash and exposing it to the action of damp air we could obtain a constant formation of ozone. The making of ozone by pouring sulphuric acid upon the permanganate of potash was liable to cause an explosion, especially if a closed flask were used. The mixture recommended by him was free from danger of this kind. When ozone was prepared by means of the electric spark, an odor was noticeable which was absent when the permanganate and the bisulphate of potash were used, yet the substance was undoubtedly obtained equally well by the latter method.

M. DUJARDIN-BEAUMETZ gave the substance of a communication which he had presented to the Bureau of Hygiene on the best method of preparing

A DRINK FOR SCHOOL-CHILDREN DURING THE HOT WEATHER.

A beverage of this kind should be healthful, cheap, and at the same time not very pleasant to the taste, as it might then be consumed in too large quantities. These qualities were possessed by a liquid containing gentian or quassia, licorice, mint, sugar, and citric acid. Its preparation cost about a cent a quart.

M. CAMPARDON said that thirst might be easily assuaged by chewing shavings of quassia wood occasionally.

M. BLONDEAU made a statement concerning the value of

SULPHURIC ACID IN CHOLERA.

He said that during the last epidemic in England very general use was made in some places of sulphuric acid lemonade flavored with tincture of orange peel, and not one of those who took this regularly was attacked by cholera.

M. LIMOUSIN said that there were several chemically incompatible formulæ published by the Bureau of Hygiene. Sweet and bitter substances were added to acids and alkalies in a hap-hazard sort of way. It would seem as though such mixtures ought to be useless. Yet if, in practice, the desired result is obtained, we ought to be satisfied.

M. BUCQUOY regretted to hear the use of boiled water recommended. This was not healthful and was liable to cause digestive troubles.

M. DUJARDIN-BEAUMETZ said that the boiled water could be recharged with air by shaking it, but it was evident that in this process it would also become charged with the germs floating in the atmosphere.

This was the last meeting of the Society before the summer vacation, but the President announced that special meetings would be called from time to time, if events of importance requiring discussion should arise. The Society then adjourned subject to the call of the President.

THE SURGICAL SOCIETY OF PARIS.

Stated Meeting, July 23, 1884.

M. MARC SÉE, PRESIDENT, IN THE CHAIR.

(Special Report for THE MEDICAL RECORD.)

THE Society having been called to order by the President, M. MONOD recalled a paper, read at the last meeting, on exostoses of the frontal sinus, and related an instance in which an

OSSEOUS CYST OF THE FRONTAL SINUS

had been taken for an exostosis. Dr. Rouge, thinking that such was the case, cut down upon it and was surprised to find himself in a cavity with very thick bony walls, at the bottom of which was a little tumor about the size of a cherry. The tumor was not disturbed, and had not increased any in size in the fourteen years which had since elapsed.

M. TRÉLAT requested that further details of this case be obtained, so that a certain diagnosis might be established.

M. CHAUVEL then read a report upon a monograph of Dr. Poulet on the subject of

TUBERCULAR AND SYPHILITIC OSTEITES OF THE SKULL.

The author passed briefly in review the subject of simple traumatic osteitis, the characters of which it is easy to reproduce experimentally in animals, and then took up the question of the specific forms of osteitis, especially the tubercular and the syphilitic. Although osseous tuberculosis is a common enough affection, tubercle of the cranial bones is, if one may judge from the number of reported cases, a very rare condition. M. Poulet, however, claimed to have found two instances of this disease among the specimens in the museum of Val-de-Grace, but the reporter took the liberty of doubting this until further proof should be forthcoming. The author endeavored to show that this affection was most truly specific, as well in its symptoms as in its pathological characteristics. The specific nature of the second variety of osteitis, the syphilitic, was incontestable. M. Poulet was able to show from a careful examination of numerous pathological specimens that the course of the disease was always the same. Starting from the pericranium, the gummy process invades the bone in the form of a spiral the turns of which become constantly larger. In the skull this spiral increases laterally like a watch-spring, while in the long bones of the extremities it increases in depth like a corkscrew. The border of this spiral is formed of very dense, eburnated bone. The monograph was accompanied with a number of well-executed designs showing the lesions referred to.

M. BOUILLY then read the history of a case of

PAROVARIAN CYST OF THE RIGHT SIDE

reported by Dr. Jeaunel. The patient, thirty-five years of age, in a good state of health, presented the signs of a monolocular cyst of the ovary. The aspirator was introduced and nearly sixty ounces of a perfectly clear fluid were withdrawn. Three months later a second operation was necessitated by reason of a reaccumulation of fluid. After aspiration of about seventy ounces of fluid, the sac was washed out with thirty ounces of a one per cent. carbolic acid solution. Then an injection of a warm solution of tincture of iodine and water, equal parts, was thrown into the cavity of the cyst. When nearly nineteen ounces of this mixture had been injected, the action of the aspirator was reversed in order to draw

the fluid back; but not a drop returned. At the same time the patient became unconscious, though very restless; the face was blue, the pulse at the wrist was almost imperceptible, and the body was covered with a sticky perspiration. The respirations were slow, irregular, and noisy. The woman was suffering most evidently from

ACUTE IODINE-POISONING.

The aspirator needle was withdrawn and reintroduced several times but no fluid could be drawn off. Numerous hypodermic injections of ether were made, mustard plasters were applied to the chest, and an electric battery of forty cells was employed. But the patient did not recover consciousness and the power of speech until thirty-five hours had elapsed. She then suffered from very marked symptoms of iodism in all the mucous membranes, the symptoms persisting for two weeks or more.

The author emphasized the fact, as shown by this case, that very grave accidents may follow an operation apparently so simple as this. He thought it would have been better for the patient had ovariotomy been performed in the first place. M. Bouilly agreed with him in this last conclusion, and remarked that this case proved that, contrary to the generally received opinion, parovarian cysts were not always cured by a single puncture.

M. Tillaux could not understand why the aspirator should be used in cases of this kind, for it only favored an arrest of the stream, as happened in this instance, by sucking the wall of the cyst against the point of the needle. He thought the amount of tincture of iodine injected (over nine ounces) was enormous. The formula that had been recommended for use in such injections was one part tincture of iodine to two parts of water.

M. Lucas Championière favored operation in the treatment of parovarian cysts. In the case cited by M. Jeannel, the patient had undergone a number of operations more serious in the aggregate than ovariotomy, and yet she was not radically cured.

M. Bouilly thought that the amount of iodine used was certainly too great, but he thought the symptoms were not those of poisoning, but were caused rather by the traumatism of the operative measures employed. He did not agree with the last speaker in his preference for ovariotomy. He thought it better to make one or two punctures at least before resorting to operation.

He then read another report on a paper by Dr. Leriche, entitled

THREE SUCCESSFUL OVARIOTOMIES.

In two of the cases the pedicle was fastened externally, instead of being abandoned in the abdominal cavities, as is usually done. He did not favor catgut for ligatures, as it could not be drawn tightly enough.

M. Tillaux had formerly used catgut, but had abandoned it for silk after having lost a patient from hemorrhage caused by the slipping of the ligature.

After some further discussion on the relative merits of catgut and carbolized silk, M. Verneuil related a case of

NASO-PHARYNGEAL POLYPUS.

The patient had been exhibited at a meeting of the Society four months ago. He was then suffering from an enormous recurrent tumor, the first operation (removal of the upper jaw) having been performed one year before. The tumor was exceedingly vascular, and a bruit was distinctly audible. The attempt was first made to treat it by means of irritant injections, but these were without result. It was then decided to tie the common carotid. This was easily done and was followed by reduction in size of the tumor, subsidence of inflammation, and relief from pain. A small abscess formed, however, at the point of incision, and was opened by M. Kirmisson, and a drainage-tube was inserted. The opening did not cicatrize, and six weeks after the ligation of the artery the patient had an attack of erysipelas. This was recovered from, but the wound began to slough, and a number of hemorrhages occurred from which the patient finally succumbed.

At the autopsy there was found to be perforation at the bottom of the sphenoidal fossa, through which a lobe of the tumor had passed into the cranial cavity. There had, however, never been any cerebral symptoms. The peripheral extremity of the carotid artery was completely occluded, but it required a long search before the string-like remains of the cardiac extremity could be found.

M. Trélat thought that palliative operations might lead to a perfect cure of naso-pharyngeal polypi, as many of these tumors underwent spontaneous disappearance in the course of time.

M. Lucas Championière said that, according to Lister, arteries should never be tied with silk, but with some substance which is capable of being absorbed in the tissues. The case just related emphasized the wisdom of this procedure, for no wound in which a silk ligature remains can be with absolute certainty aseptic.

M. Tillaux presented a patient upon whom he had performed

RESECTION OF THE SUPERIOR MAXILLA

on account of a sarcomatous tumor, the size of a small ostrich egg, filling the entire zygomatic fossa. The patient made an excellent recovery, and, by means of an apparatus made by M. Beauregard, could masticate with great ease.

The meeting then adjourned.

International Medical Congress.

EIGHTH SESSION.

Held at Copenhagen, Denmark, August 10–16, 1884.

REPORTS OF SECTIONS.

(Special Report for The Medical Record.)

SECTION ON OPHTHALMOLOGY.

Dr. Samelsohn, of Cologne, read a paper on the

PRACTICAL VALUE OF LIGHT SENSE IN OPHTHALMOLOGY.

If the examination of the light sense in practical ophthalmology has not hitherto met with the attention it undoubtedly deserves, it is from the want of an efficient mode of testing it. The methods hitherto in use depend on testing the vision either with diminishing or with constant illumination. The first method was much used by Förster, who formulated the law that the *light sense* is only impaired in affections of the percipient elements, while affections of the conducting elements are indicated rather by an increased sensibility for objective light. A large number of examinations made during the last two years have convinced the author that the law of Förster has only a very limited application.

Although disease of the percipient elements of the retina very often results in a considerable impairment of the light sense, yet the converse is not so often true that one can, from the fact of the light sense being impaired, diagnose a disease of the percipient elements. Indeed, inflammatory affections of the optic nerve cause so great a diminution of the light sense that in certain affections it amounts almost to torpor of the retina.

DESCRIPTION OF THE CONDITION IN CERTAIN FORMS OF DISEASE.

From this it is seen that the light sense is very much more affected than the quantitative color sense; the latter, on the contrary (as shown elsewhere), stands in the clearest numerical relation with the light sense. The testing of the light sense is useful for differential diagnosis under the following circumstances: (1) In certain forms of opacities of vitreous, which may be mistaken for detachment of the retina; (2) in differential diag-

nosis between simple glaucoma and optic atrophy; (3) as giving indication for diagnosis and prognosis in certain forms of cataract.

Prof. Schmidt-Rimpler, of Marburg, read a paper on

A NEW METHOD OF DETERMINING REFRACTION BY MEANS OF THE OPHTHALMOSCOPE.

In this method he did not make use of the image of the retina itself, but observed the image of the source of light (lamp) thrown upon the fundus, the same image that forms the object of investigation in so-called retinoscopy, except that in the latter no convex lens intervenes. The apparatus used in Professor Schmidt-Rimpler's method consists of a convex lens, from which an arm projects to keep it at such a distance from the observed eye that its focus and the first principal point of the eye coincide. A tape measure on the opposite side of the lens determines the distance of this lens from the concave ophthalmoscopic mirrors, from which data the distance between the principal focus of the lens and the inverted image of the source of light reflected from the concave mirrors is known. This distance, expressed in centimetres, gives the amount of ametropia in terms of a dioptric, myopia to the one side of the focus of the lens, and hypermetropia to the other. It was plain that if the eye examined were emmetropic, and its accommodation at rest, the best defined image of the source of light would be obtained when the focus of the concave mirror coincided with that of the convex lens, as it was at that point that the inverted aërial image of the fundus was situated. In myopia the focus of the concave mirror must lie nearer to the lens than the focal length of the lens, in order to obtain the best definition, and in hypermetropia it must lie further from the lens than the focus of the latter. When the lens was so placed that its focus coincided with the principal point of the eye, equal movements of the external source of light along the optic axis corresponded to equal differences of refraction in the observed eye. The strength of lens used was 10 D, and in that case every alteration in the refraction amounting to 1 D altered the position of the aërial image of the fundus 1 centimetre.

Dr. Noyes, of New York, did not rely entirely upon the ophthalmoscope; he always tried the use of glasses in confirming his diagnosis. He had a clip upon his own ophthalmoscope in which he could easily place a cylindrical lens for examining the fundus.

Mr. Berry, of Edinburgh, approved of Professor Schmidt-Rimpler's method because of the difficulty of testing by the direct method in *high degrees* of ametropia. He had found that the refraction of the eye was different at the yellow-spot and the optic disk regions.

Mr. Yuler, of London, said that he should be glad to become practically acquainted with Professor Schmidt-Rimpler's new method. With regard to the estimation of refraction by the direct method of ophthalmoscopic examination, he was of the same opinion as Mr. Berry and Dr. Noyes, viz., that in simple hypermetropia and myopia of low degree we were able to see the yellow-spot region, and so to estimate the refraction on the visual axis; but when astigmatism existed, the direct method failed because of the paucity of vessels in the yellow-spot region. He considered the shadow-test (retinoscopy) to be the best and most exact means of estimating the refraction in astigmatism, but this must be done only when the eye is fully atropised and the patient is looking straight at the observer's forehead. By this means the refraction of the visual axis could be accurately estimated.

Dr. Hansen Grut, Prof. Sattler, and Prof. Liebrecht also joined in the discussion, and Prof. Schmidt-Rimpler replied.

Dr. Edm. Hansen Grut, of Copenhagen, read a paper on

TWO FORMS OF KERATITIS.

1. The first form was bullous keratitis following traumatic abrasions of the corneal epithelium. The painful and transient attacks which come on sooner or later after an abrasion are well known. They have been wrongly called nervous. They are always occasioned by a mechanical cause, generally at the moment the patient awakes. This mechanical cause is the friction of the eyelid against the eye, owing to the moisture which comes during sleep, and the rubbing with the fingers by the patient, who fancies that there is a foreign body in his eye. The nerves of the epithelium remain in an unhealty condition—perhaps the regeneration of the epithelium is defective—despite the apparently normal appearance of the eye. A slight traumatism would suffice, then, to provoke a bad attack. Sometimes, and oftener than one thinks, it is real keratitis which takes place. This keratitis always returns to the bullous form. Most frequently the bulla is difficult to see directly, but can always be seen by withdrawing the anterior surface of the epithelium by means of iris forceps. The bulla is always extensive, in some cases occupying more than half the corneal surface. Bullous keratitis is not always allied to a glaucomatous condition, or to other serious affections of the eye.

In some cases there is a symmetrical eruption in the other eye, even, although there is absolute certainty that this eye has not been previously injured.

2. The second form was one of slow progress accompanied by very slight subjective symptoms, and having hardly any vascular injection. There is a slight grayish infiltration, difficult to see, having a tendency toward serpiginous increase. It spreads by slight projecting nodules, which are more densely infiltrated than the rest. The affection always remains superficial. Neither the deep layers of the cornea nor the iris are ever invaded. The affection is undoubtedly of mycotic origin.

On the 12th, Prof. Meyer presiding, Dr. Radard, of Paris, read an interesting paper on

THE TESTING OF VISION OF RAILWAY EMPLOYEES.

Dr. Liebrecht read a paper on the same subject, and a third was read by Dr. Fox, of Philadelphia, for Prof. William Thompson.

Prof. Sattler, of Erlangen, read a paper on our actual standpoint with regard to the conception of diseases of the conjunctiva and of

THE NATURE AND THERAPEUTICAL ACTION OF JEQUIRITY.

With regard to jequirity, Professor Sattler's experience was that the infusion of this drug was very beneficial in granular affections of the conjunctiva. In all cases he found the characteristic bacillus in the infusion used. In some cases lesions of the cornea were produced, especially by frequent repetitions of the process in rapid succession. For this reason he thought it not safe to use the drug in cases where the cornea was unaffected.

Dr. Benson, of Dublin, had used jequirity infusion in upward of fifty cases, and had found it very beneficial in granular conjunctivitis and pannus. In some cases he could find no trace of the bacillus in the infusion used.

Dr. E. Meyer, of Paris, read a paper on

THE ARTIFICIAL MATURATION OF CATARACT.

The chief points of his paper were as follows: The opacification of the whole of the lens substance, which alone admits of its complete expulsion, is a desideratum in the normal extraction of cataract. In cases where extraction of incomplete senile cataract is compulsory, this artificial maturation is indicated. The best known method of maturation is that of massage of the crystalline lens through the cornea (Förster) after the evacuation of the aqueous humor from the anterior chamber.

Iridectomy, he said, was of great importance. The pressure should be made with an instrument (shown) which made it general all over the cornea, and not localized. He showed a rabbit (living) in which he had produced cataract by this massage two days before, in the presence of several members of the section. The lens

of the rabbit was now quite opaque in the upper part, and partially so all over. There was no marked inflammation of the rabbit's eye. Professor Meyer was not prepared to state the exact pathological process by which this opacity was brought about.

Dr. Mooren, of Düsseldorf, criticized the operation; he had lost one eye by this method, and was less sanguine of its success than Dr. Meyer appeared to be.

Dr. Samelsohn, of Cologne, had tried it in a number of cases in some of which there were only cortical opacities. Some of his cases had succeeded, some not.

Dr. Abadie, of Paris, objected to the operation because of the difficulty of inducing patients to submit to so tedious a process.

Prof. Gayet, of Lyon, read a paper on the

RESULT OF GREAT LOSSES OF SUBSTANCE OF THE CORNEA.

The opening of large abscesses and the constant washing of them constitute a mode of treatment more advantageous, and for which one cannot be too grateful to those who have laid down the principle of it. Unfortunately, if the eye is permanently saved, it is not protected from progressive staphyloma, large adherent leucomas, synechia of the iris, and cataracts. Surgery has certainly preserved the organ, but for the most part it has preserved a useless organ, when it is not injurious, either through the pain it causes or from sympathy which it engenders. I think, with the help of certain facts, that it would perhaps be possible to substitute for the simple opening of the abscess a peripheral of the cornea with a large iridectomy.

Dr. Boucheron, of Paris, read a paper on

THE USE OF ATROPINE AT THE COMMENCEMENT OF CONVERGENT SQUINT.

The chief points of this paper were as follows: At the commencement of convergent strabismus the prolonged use of atropine in both eyes appeared to be the best means of treatment, because it counteracted the instinctive and excessive efforts at accommodation in a young ametropic child, in its first attempts at near vision. The amount of atropine used must be sufficient to cause paralysis of the accommodation and extreme dilatation of the pupil. Atropine was only efficacious during the period in which the strabismus was intermittent, that is to say, during the time when secondary retraction of the internal rectus was absent. This period was very short. A favorable condition to the cure by atropine is found in the rapid growth of the infant, especially in the development of the face, and more particularly the enlargement of the ethmoid bone, because such development brings about a separation of the orbital axis and a diminution in the strength of the convergent muscles.

The advantageous result of the atropine cure being applied from the commencement of convergent strabismus is caused by the rapid restoration of the eye from deviation, thus often saving it from becoming amblyopic. When it is, as we think, the consequence of an arrest in development of the macula after birth and consecutive to deviation of one of the eyes, electricity is often very useful. The correcting glasses for ametropia may be used at the same time, or after the atropine cure, to guard against any relapse. If "amblyopic exanopsia" has been avoided by using atropine and electricity, the bandage or the glasses are less frequently used. Tenotomy is always the best treatment for *permanent* squint.

Inconveniences from atropine—special intolerance, conjunctivitis—are very rare with young children; they are avoided by the use of the first remedies, and by changing the mydriatics when ill-supported. The myotics which contract the muscles of accommodation, in suppressing also the instinctive and exaggerated efforts of the accommodation equally produced, as he had already pointed out, very favorable results in the early squint, but the myotics appeared to him less active than the mydriatics.

Mr. Yuler, of London, thought there was much in the paper demanding the consideration of ophthalmic surgeons. With regard to the second point in Dr. Boucheron's paper, he had tried atropine in many cases of convergence, and while it had often succeeded in curing the intermitted cases, he had never once found it sufficient to remove a squint which had become permanent. He always corrected the ametropia at the time and before discontinuing the use of the atropine.

Dr. E. Hansen Grut read a paper on

LATENT STRABISMUS, ESPECIALLY LATENT DIVERGENCE.

Latent divergence is not *paresis*, neither is it muscular weakness. With just as little reason can it be attributed to increased power in the external recti. It depends on a defective impulse to convergence. The expression "loss of muscular power of internal recti" is erroneous, and does not express the true state of the case. It is the relation between convergence and accommodation which chiefly determines the latent condition of the covered eye. In order to estimate the latent position two things are absolutely necessary: 1, Accurate accommodation for the point of fixation; 2, an absolute condition of rest of the eye in looking at the distance.

Fusion is possible in spite of latent divergence. Usually correct fixation can be maintained, so that generally, even with very pronounced latent divergence, there is no convergence asthenopia if the power of fusion is good. A defective power of fusion renders difficult or prevents maintenance of exact position. In this case there is no effort which would lead to muscular fatigue, but diplopia. If there is good power of fusion, but great divergence in condition of absolute rest, an effort to converge is made, but by no means so often as is usually thought. Clinical experience alone can determine how often and when muscular asthenopia is present. The frequency of muscular asthenopia has become very great, and our means of diagnosing its presence are somewhat defective. In the first place the symptoms of muscular asthenopia are extremely variable, and not nearly as easy to classify as those of accommodative asthenopia. Numberless cases of nervous asthenopia are erroneously diagnosed as muscular. The relation between the available power of adduction and the degree of latent divergence is not sufficient to indicate whether muscular asthenopia is present or not. The same is true of exclusion of one eye during work and of the employment of prisms. The slight degrees of latent divergence (under 16°) cause muscular asthenopia, almost without exception. The most delicate tests for measuring accurately the *degree* of the latent divergence are uncertain, and are moreover superfluous.

An operation is only justifiable when there is more latent divergence in condition of absolute rest. The operation is, therefore, performed rather on account of latent absolute squint than for insufficiency. It is injurious to produce by this operation an absolute condition of *convergence* in the condition of rest, even though the power of abduction may still be sufficient to overcome the homonymous diplopia at the time.

Mr. Yuler, of London, gave demonstrations in the Section of Ophthalmology of

(1) FROST'S ARTIFICIAL EYE.

This is an excellent instrument for teaching purposes. It is provided with two movable retinæ, one of glass and the other painted so as to represent the normal fundus. By means of a delicate screw the eye can be shortened and lengthened so as to represent hypermetropia, emmetropia, and myopia, respectively, and by then adding a cylindrical glass to the front of this it becomes astigmatic. All the characteristic signs of emmetropia and ametropia can be clearly taught by this instrument.

(2) M'HARDY'S PERIMETER.

This is a self-registering instrument of excellent workmanship. It is self-registering and combines the proper-

ties of Förster's instrument. It is a decided improvement upon the perimeter shown at the London Congress by Stevens.

Both McHardy's perimeter and Frost's artificial eye can be obtained of Picard & Curry, London.

Dr. Noyes, of New York, read a paper on

ASTHENOPIA FROM INSUFFICIENCY OF THE EXTERNAL RECTI MUSCLES.

He spoke of the small degree of attention which had been given to this topic in text-books and in journals. While the varying degrees of accommodation appropriate to given amounts of convergence had been carefully studied by Donders and others, and that too in various states of refraction, there had been very little study of the degrees of muscular effort which belong to special amounts of accommodation. The latest and best contribution is by Bissinger under the auspices of Nagel, but this is brief and he confessedly leaves much to be done. In the study of asthenopia Dr. Noyes attempts to find the real conditions of muscular power, both with and without accommodation. He tests the adduction and abduction both for the working distance and for six metres. He does this in both regions with the glasses which the patient may require. He employs Graefe's equilibrium test in both regions, but he finds it of very uncertain value. Inasmuch as all the cases which he studied were asthenopic and therefore were in a pathological condition, he found that the relations between accommodation and convergence had been in many instances entirely disrupted. So frequently was this the case that he adopted the plan of resorting to atropine in very many cases, and in all those which were attended with severe pain. He found it necessary to do this to bring to view the real ability of the muscles in adduction and in abduction, and he was also obliged to wait in many instances for the mydriasis to subside before the ultimate and true status could be ascertained. It is rare that one examination will suffice. By a process both of analysis and of synthesis, that is of examining the functions separately and in combination with each other, he found that he could with greater certainty arrive at the truth. The mydriatic not only aided in making a diagnosis but was also a therapeutic measure.

Dr. Noyes had brought together 83 cases of asthenopia from insufficiency of the external recti. The largest number (viz., 30) were among hypermetropes, while emmetropes (viz., 20) came next in frequency, then cases of astigmatism (viz., 18), and lastly, 15 were myopes. A number of cases included in the report were found to consist essentially of spasm of accommodation, but this was associated with and in reality caused by debility of the externi. In all asthenopic cases Dr. Noyes looks for spasm of accommodation, and if it exist in notable degree this becomes an absolute indication for atropia to full paralysis of A.

What degree of deficient abduction, or what disproportion between abduction and adduction shall be accounted abnormal cannot be dogmatically asserted. The existence of pain in use of the eyes, not relieved by suitable glasses or by atropia, or by attending to other well-known concomitant conditions, was sufficient reason to resort to the local treatment which had been most often successful, viz., the employment of prisms with the bases outward, amounting as a total to three or six degrees, to be worn in most cases all the time, both for the distance and for the near.

Dr. Noyes clearly discriminated between the asthenopic cases in which the muscular trouble was entirely reflex and the product of remote disease, as of the uterus, lungs, etc., and those in which there was an idiopathic weakness of the muscles. In the former cases local measures were of minor value, while in the latter they were of notable advantage. There are also mixed cases which are both reflex and idiopathic. In only five cases was tenotomy performed—in four with entire success, in one without success.

A point to which Dr. Noyes called attention was the latent character of insufficiency of the externi, and especially to the fact that in some of the cases which proved by experience to be insufficiency of the externi, the evidence furnished by Graefe's equilibrium test pointed to insufficiency of the *interni*. He did not refer to myopic cases, but to other forms of ametropia and to emmetropia. In these relief was secured by wearing constantly, and both for near and far vision, *adductive* prisms, while in a very few cases abductive prisms were used for the near vision and adductive prisms for distance. These cases were noticed by Graefe and by many others since his time. They have divergence for the working distance, and convergence or perhaps equilibrium for the distance of six metres when examined by the equilibrium test. Some of them are truly cases of latent or manifest insufficiency of the externi, and if treated as such they recover. Dr. Noyes desired to call attention to this mode of regarding them, which had proved of great importance in his own experience, and which he believed would be found to be the solution of some difficult and not infrequent cases.

Of the 83 cases the results of treatment were known in 65.

Patients having—	Cured.		Relieved.		Not relieved.		Totals.	
		per cent.		per cent.		per cent.		per cent.
Hypermetropia, 28 cases...	11 = 39		12 = 43		5 = 18		28 = 100

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE MEDICAL ACT AND THE LICENSING BODIES—LONDON AND EDINBURGH UNIVERSITY EXAMINATIONS—THE SOCIETIES—HOSPITAL SATURDAY—DECREASE OF SMALL-POX—THE INVENTOR OF CHLORODYNE.

London, September 13, 1884.

The Medical act having been withdrawn by the Government, all the examining bodies are free to pursue their career unchecked for at least another year—probably for several years. These comprise (within the United Kingdom) eleven universities and nine corporations, but as for many years past one university (St. Andrews) has almost ceased to give degrees except to those already qualified and on the register, and the Edinburgh Colleges of Physicians and Surgeons have lately agreed to only give their diplomas jointly in future, the portals by which the profession may be entered now only number eighteen. These are more than enough for a profession of only twenty-five thousand members. The mischief consists more in the inequality of the tests imposed by these various bodies. Even the universities vary greatly. An M.D. Edin. is very different from an M.D. Lond. At Edinburgh, at all except the final examination for the M.B. degree, if a candidate fail only in one subject he is allowed to go up again in that subject alone in a few months' time. One or two failures in single subjects do not, therefore, necessarily prolong his curriculum. I am informed that even at the final examination, should a candidate do badly at his clinical he is allowed to have a second chance before being finally rejected. If then unsuccessful he has to wait twelve months before going up again.

At the examinations for the London University M.B. degree, failure in only one subject is fatal. The whole examination has to be passed over again, including those subjects in which the candidate was previously successful. With the exception of that for matriculation, the

examinations are only held once a year, so each failure involves a year's delay.

Without discussing the question of whether the London University examinations are harder in themselves than the Edinburgh ones, these differences obviously render the Edinburgh degree easier of acquirement. Some choice also is allowed at the earlier examinations there as to what subjects to be examined in at once. At the London the only option now allowed is in physiology, that lately offered at the preliminary scientific examination being now rescinded. I think, though, on the whole there cannot be much doubt that the "London" is more exacting than its Northern sister. With all the advantages offered in our London schools, the proportion of London students who graduate at it is very small.

The medical societies will soon begin their meetings again. A practitioner who attends several societies regularly finds a distinct gap made in his winter evenings. Four of them, viz., the Medico-Chirurgical, Clinical, Pathological, and Obstetrical, meet in the same rooms on different evenings. It has been proposed to amalgamate these, and perhaps the Medical Society also, under the title of the "Academy of Medicine," with of course different sections. This arrangement would have many conveniences, but although it has several times been proposed nothing has come of it as yet. One practical difficulty consists in the varying rates of subscription of the various societies. Another would be found in arranging the division of the property held by them. The Medico-Chirurgical possesses what is considered to be the best medical library in London, and its Fellows are allowed to take the books home to read. The Obstetrical Society also owns a very good library. The Dublin societies have, however, united to form the "Academy of Medicine in Ireland," with four sections and two sub-sections. so perhaps the London societies may yet see their way to follow suit.

Hospital Saturday has been so unsuccessful this year that it is proposed to have a second one this day fortnight. At its best it has never been as successful as the Hospital Sunday Fund. Last year the "Sunday" brought in more than three times the amount of the "Saturday" fund.

Small-pox is rapidly decreasing. Last week only twelve deaths from it occurred in London.

Dr. Collis Browne, the so-called inventor of chlorodyne, has just died. Chlorodyne is perhaps the only patent medicine and secret remedy which has been largely employed by medical men. The makers contended that it contained a certain alkaloid which gave it valuable properties. They declared that this could not be discovered by analysis. This proved to be so far correct that many people were inclined to regard the "alkaloid" as a myth. Several lawsuits have been waged over chlorodyne. The final result was to leave the original inventor, Dr. Browne, in undisturbed possession of his rights. He derived a large income from the sale of the preparation.

CENTRAL EUROPE IN A CHOLERA SUMMER —THE CLEANLINESS OF PARIS AND LONDON—THIRD INTERNATIONAL CONGRESS OF OTOLOGY, IN BASEL.

To the Editor of The Medical Record.

SIR: I would not advise even a medical man, who desires a vacation in Europe, unless he is specially interested in the germ theory, to choose a summer in which Asiatic cholera is epidemic in a few places, and is about to become epidemic in a great many more. But, to the passengers landing at Southampton on June 26th, the announcement that cholera had broken out in Toulon, and that it would undoubtedly spread over France and throughout Europe, was like thunder from a clear sky. Many a prophet has lost what reputation he may have had by predictions as to how and where the cholera would extend. The July fête was to bring it to Paris. The fête was held, but no cholera came. Refugees from Toulon and Marseilles came to Paris by the hundred; some of them to the very hotel from which this letter is written. No quarantine was established. People were not even disinfected, but Paris has been kept strictly clean, and if the cholera has reached it at all, it has only been in a few sporadic cases, as yet scarcely worthy of specific attention. On the other hand, poor Italy has rigidly maintained a quarantine extending even to the peaks of almost inaccessible frontier mountain tops, and maintained it actually at the point of the bayonet. She neglected, however, to clean Spezzia and Naples, and, as we all know, she is suffering from an epidemic as ruthless as that which depopulated and impoverished the cities and villages of Southern France. The condition of Naples, at the time of the late outbreak, was the same as that which has given it a pre-eminence among filthy cities. There was not enough water for personal or public cleanliness. Cesspools existed in nearly all the houses in the poorer parts of the city. Their solid contents were kept for months, while the fluid oozed away in rather small channels. Their zeal in this direction was occasioned by a desire to enrich their vine and olive yards. A great storm, occurring just before the outbreak, caused many of the outlets of these cesspools to overflow, with effects that it does not require a medical mind to imagine. To return to the prophets for a moment. It is said that an English physician got a guinea early in the season for advising an American lady, who had come to Europe for a prolonged stay, to sail for home in the first steamer, because, as he believed, the cholera would soon be in England, and then the steamers to America would cease running. As a matter of fact, travelling in Central Europe this summer, barring the very hot weather, has been pleasanter than usual.

It is true those who trust to the opinions and fears of the average public must have had many misgivings. We were warned not to go to Vienna, because the cholera was just about to break out there. As you know, there has not been a single case in that city. Then, again, we were told that Switzerland would be packed full of people and very unhealthy, but Switzerland was not full, and was never healthier. Poor Geneva was almost bereft of American and English visitors on account of the repeated statements that the cholera had actually broken out there. I think Americans, as a rule—those who did not turn back to enjoy the earthquake—went to Scandinavia, Ireland, Scotland, and England. Occasionally one, not able to resist the blandishments of Paris, stole over from dirty London to that most cleanly city. We, in Central Europe, have had exceedingly good rooms, attendance, and very civil landlords, but a very hot summer. A few travellers have been disinfected at Geneva, but it seems to have been rather a source of amusement than of actual annoyance. I think it remains to be proven that quarantine or disinfection are of the slightest service. If cholera be a contagious disease, then it is very singular that the most of France, all of Germany, Austria, and Switzerland have thus far escaped the epidemic, while fugitives from Toulon and Marseilles have been running with their bag and baggage all over these countries without let or hindrance. I suppose the ravages of the disease at Naples can hardly be exaggerated, but if our newspapers would cease to put panic-striking head-lines over the paragraphs in regard to the spread of the cholera, and reserve their rhetoric for appeals for personal and public cleanliness, much could be done to arrest the progress of an epidemic, the cause of which we know to be chiefly founded in dirt. It is possible that, despite the Berlin conference and its opinions, we shall all yet believe that cholera Asiatica, cholera nostras, and cholera morbus are one and the same.

The man in Tennessee about whom I read in a New York paper, and the one in Ireland, may actually have had cholera like that of Naples. The results of British cleanliness in India seem to indicate that cholera may often be

expected where great heat, public and personal filth exist in the proper combinations. As has been already intimated, this letter is written from Paris. I have never had a proper idea of how a great city may be kept clean until I saw Paris as it is this summer. Clear water actually flows through the gutters and over the streets two or three times a day. The poor quarters are as clean as those in which the rich live. London bears no comparison to the French capital in point of cleanliness. In fact London seems to me, in this latter part of September, by no means a clean city. Cleaner than New York it certainly is, and I read in the English papers that they are cleaning up everywhere. One of her eminent sanitary authorities states that cholera in England always saves more lives than it takes, since it lessens the mortality from typhoid fever for a year; the cleaning being too late for one purpose, but in time for the other. I hear great things of the cleansing which has been undertaken in New York this summer. It is to be devoutly hoped that it is all true. With the standard of cleanliness that has hitherto existed among our rulers, and with our bad pavements and our scarcity of water, I doubt very much if New York is yet clean. Our passengers will be convinced if, when landing from the ocean steamer, we are not regaled with the usual sights and smells of Canal and Christopher Streets, and Seventh Avenue. Perhaps the medical profession of New York could not do a better work this winter than in preparing for the cholera of next summer by organizing a street repairing and cleansing society. Whatever other lessons this season of cholera has conveyed, this one stands out pre-eminently, that in cleanliness, personal, household, and municipal, are to be found the only preventive means, while quarantines and disinfections are but delusions and snares.

Many of the readers of THE RECORD may have forgotten that the first International Congress of Otology was held in New York in 1876. It was very sparsely attended by Europeans. Indeed, I believe but one paper was read for a foreigner. The Congress was held in the same year with the International Medical Congress in Philadelphia and the International Congress of Ophthalmology in New York. There was a volume of Transactions published, however, and a second Congress was held in Milan in 1880. The third has just taken place in Basel, from the 1st to the 4th of September. Basel has a small university, but one of renown. Vesalius taught anatomy there, and it has furnished several great teachers to other universities. Through the efforts of Professor Burckardt-Merian and Professor Politzer, Drs. Lowenberg, Ménière, and others of the Committee of Arrangements, the Congress was a success in numbers and in the character of the papers read. More than eighty names were inscribed on the roll, among which were Moos, Bezold, Pritchard, Politzer, Delatouche, Ménière, Gelle, Lowenberg, Guye, Colladon, Hartmann, Kuhn, Sapolini, and Valentin.

The Governments of Switzerland and of Basel were very courteous and hospitable. The social entertainments—public breakfasts and dinners—were of a charming kind. The speeches of the representatives of the municipal and State authorities were even eloquent. In fact, it seemed to me that the manner of speaking of our Continental brethren, both in the Congress and at the social entertainments, was singularly happy. Some of the speakers read their papers while sitting, after the manner of German professors in the lecture-room. This seemed to me to contribute materially to the ease of the delegate reading a paper. The discussions were lively in the extreme, as well as polyglot. French was the leading language, since no Frenchman ever appears to understand or speak any language but his own. Burckardt-Merian, Politzer, and Moos gave some very fine anatomical and pathological demonstrations. The papers read in French were epitomized in English and German by Guye and Lowenberg, who were the volunteer interpreters for the Congress. At some points the sounds at the dispersion from the tower of Babel were possibly reproduced. I am sure many of the readers of THE RECORD will be interested in the volume of Transactions.

The next session of the Congress is to be held in 1888 in Brussels. A telegram was read from the mayor of that city welcoming the meeting in advance. A proposition to meet in Washington, as a part of the International Medical Congress, found no favor, otology being considered to be a plant which requires a whole garden, and not a mere plot, to itself.

PARIS, September 12, 1884. D. B. ST. JOHN ROOSA.

"ON THE ARREST OF TUBAL PREGNANCY BY GALVANISM."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In reading Dr. Mundé's interesting case, in the last issue of THE RECORD, entitled "A Successful Case of Arrest of Tubal Pregnancy by Galvanism," I noted both a point for discussion and a mistake to correct. I am all the more ready to avail myself of any opportunity to extend the consideration of this subject because it is an accident so comparatively infrequent that it is only occasionally that the immense value of electricity in saving life in this condition is brought to the attention of the profession.

Considering the number of successful cases that have been reported, it is indeed surprising that one meets with so many physicians who have either never heard, or who have forgotten the fact, that electricity offers a safe and speedy relief from this dreaded abnormality of pregnancy.

Dr. Mundé raises the question as to the form of current most suitable in these cases, preferring faradism, and basing his preference on the satisfactory use of it in several cases by others, and on the fact that in his own case prolonged and alarming prostration followed the use of galvanism.

If these cases were recurring with great frequency, experience would soon decide which was the surer and safer method, but as they are relatively so infrequent, physical and physiological laws must partially guide us. We know that galvanism is a far more potent agent than faradism in its relation to living tissue, and more destructive to life, and so has an advantage over the faradic current. As to the effects of the application on the mother, I am persuaded that they never need be harmful, or especially painful, no matter which form of current is used.

In his own case, Dr. Mundé made use of twenty-four cells, giving shocks that were "quite painful," through a séance of ten minutes. He says: "I did not think the current too strong, for I remembered that in one of the successful cases reported (McBurney's), thirty-six cells had been used." The correction that I wish to make is that, in the case to which reference is made, but twenty-three cells were used.

In six other cases where I successfully used electricity (all of which were reported in this journal), and which went to make up the eleven cases collected by Garrigues, to which Dr. Mundé refers, the current strength was much less. In two cases only twelve cells were used, and in none of them did the slightest ill effects ensue; all of which goes to show that a much weaker current of galvanism will, in all probability, prove effective than was at first supposed.

My experience leads me to believe that one-half the number of cells used by Dr. Mundé, and with an application one-half as long, would have been sufficient. His statement that thirty-six cells were used in McBurney's case was due, I suppose, to the fact that in the report it was stated that my thirty-six-cell battery was brought.

It is readily seen that it must be of vital importance to use the minimum of current strength necessary to destroy the life of the fœtus, not so much perhaps on account of the possibility, in rare instances, of its prostrating the patient, but because the stronger the current the greater the possibility of rupturing the already distended tube.

CONTRIBUTIONS TO THE ANATOMY OF THE LEMNISCUS.

WITH REMARKS ON CENTRIPETAL CONDUCTING TRACTS IN THE BRAIN.

BY E. C. SPITZKA, M.D.,

PROFESSOR OF NEURO-ANATOMY AND PHYSIOLOGY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

I.

I.—INTRODUCTION.

THE attention of those who are interested in determining the location of special functional nerve-tracts in the brain and spinal cord has been more particularly directed to the one which mediates the conveyance of voluntary impulses from the supreme centres in the cerebral cortex to the deputy centres or outposts in the anterior cornua of the spinal cord, and their analogues the nuclei of certain cranial nerves. Aside from this, only the internal capsule, empirically discovered to contain a sensorial tract in the posterior part of its posterior division,[1] and the differentiated tracts in the spinal cord have received much attention. Among the reasons which account for this favoring, the greater frequency of disease of these parts as compared with others, their easy topographical demarcation, and systemic clearness, are the chief.

It is evident, however, to those who look beyond the popular aspect of cerebral localization, that what was until quite recently a *terra incognita* to most cerebral pathologists—the brain axis—contains within its labyrinthine maze the solution of much that is enigmatical in the cerebral mechanism. Here are found, besides the important cranial nerve nuclei, and the tracts which bind these into co-ordinated reflex or automatic associate action, the great projecting fibre masses, which Meynert first attempted to systematize. Here are the channels for the transmission of special qualities of sensation, and of those obscure influences which determine co-ordination. The tracts which are more or less fused into the bifid cylinder of the cord attain greater distinctness, and separate more widely, as they pass through the oblongata and pons, in order to reach their mutually remote destinations. Many of them are inaccessible to the experimenter, and so rarely the site of limited (focal) disease, that it is improbable that their function will ever become known by the empirical but crucial tests of the physiologist and pathologist. Anatomical methods must supply the deficiency, at least for the present, and a small army of anatomists, following the lead of Gall, Meynert, Foville, and Gratiolet, and working with the improved methods of Stilling, Gudden, and Flechsig, are rapidly completing the survey of the course taken by the great nerve-tracts, discovering their ganglionic and peripheral terminations, and enabling the physiologist to infer the rôle they play in the machinery of thought and action.

In the course of these researches it has become noted as one of the most significant facts, that there is a remarkable difference in kind between the course of the tracts of voluntary motion and those which convey sensorial impressions—a discrepancy which may yet lead to a complete revolution in the views generally entertained of the central nervous functions. I refer to no less startling an innovation on the current views than the possible one, that certain of the tracts which are ordinarily regarded as sensory, and hence—almost self-evidently—as centripetal, are really the seat at the same time of centrifugal functions.

While the tract of voluntary motility directed to the extremities runs clear of all ganglionic interruption from the supreme centre, the cortex, to the gray matter of the cord, not one of the sensory tracts has been traced to a *cerebral* termination, without encountering a ganglionic interruption. The columns of Burdach and Goll, for example, terminate in the nuclei of those columns, the direct myelo-cerebellar tract runs into the cerebellum, and other less individualized fibre-systems, which may possibly have a relation to sensory functions, are connected with and provisionally at least terminate in some one or other ganglionic way-station or *terminus*.

If on comparing the relative development in various animals of the internodial ganglia connected with these tracts, it were found that they are less developed in higher than in lower animals, it might be inferred, as I urged with regard to certain other ganglia and tracts, that they represented necessary steps in phyllogenetic development, destined like the human tail, and the notochordal relic in the *ligamentum suspensorium dentis epistrophei*, to become obsolete. For nerve-tracts subservient to higher functions do exhibit a tendency to emancipate themselves from ganglionic interruptions, probably because a direct telegraphic connection—*cæteris paribus*—is a more perfect mechanism than one which has to pass many interrupting stations.

But this is not the case with regard to the ganglia under consideration. Their interrupting stations, such as the nuclei of the columns of Goll and Burdach, and the dentated nucleus of the olive, attain their highest development in man and the anthropoid apes. There is as much of higher individuality in the varying contours of the last-named body, as there is in the cerebral hemispheres themselves; just as the monkeys alone resemble man in the type of cerebral convolution, so they alone of all animals present anything like the same character, relations, and degree of olivary corrugation.[1] If there is any inference to be drawn as to the physiological importance from rela-

[1] It is surprising to find how uncertain, not general medical writers, but specialists, who have furnished accounts of the cerebral architecture, appear to be on this important head. The tracts for the control of the motor cranial nerves (with the probable exception of the oculo-motor series), and the pyramid tract, which conveys voluntary impulses to the extremities of the opposite side, as ascertained by Flechsig, are situated in and behind the *genu* of the internal capsule, that is in the anterior part of the posterior or *thalamo-lenticular* division, not in the "anterior half or two-thirds of the capsule" as Seguin (Lectures on Localization, MEDICAL RECORD, vols. xiii and xiv.) and a few others represent it. Where those who are familiar with cerebral topography, who have actually manipulated brains, besides being active as original and laborious contributors to the subject of cerebral pathology, err, it is not to be wondered at that compilers should follow. Ranney (Applied Anatomy of the Nervous System, pages 44, 48, and 91) repeatedly makes the same erroneous statement. Perhaps the loose ideas on this subject are in part due to the faulty conceptions of the situation and course of the internal capsule which such diagrams as that of Dalton, copied on page 92 of Ranney's book, are calculated to foster. Here the pyramid fibres of the capsule are actually made to decussate in the pons! It is best, in order to avoid confusion, to speak of the anterior of the two great divisions of the capsule which lies between the ecto-caudad slope of the *caudatus* and the meso-cephalic slope of the *lenticularis*, as the "caudo-lenticular capsule" and of the posterior, which lies between the meso-caudad slope of the *lenticularis* and the ecto-cephalic slope of the *thalamus*, as the "thalamo-lenticular capsule." It is in the latter alone that the "anterior" motor division and the "posterior" sensory division are located (Flechsig, Wernicke, Strümpell, etc.). The so-called external capsule, which lies between the ectal face of the *lenticularis* and the *claustrum*, might be distinguished by the term "claustro-lenticular" capsule.

[1] And this not as an expression of generally high cerebral development in the anthropomorphæ, but of affinity in zoölogical position, and, what is practically equivalent, of peripheral disposition, for the elephant and porpoise, with far more complexly convoluted hemispheres than man even, have simpler olivary bodies, resembling those of their humbler congeners, the hog and the sea-lion. Meynert is utterly at sea where he refers to the remarkable development of the olive in marine mammals, for the same elevation passes as the pyramids in Huguenin's treatise.

tive development, these interrupting stations must be regarded as important factors in the central laboratory. This is almost the same tale as that which might be told of the cerebellum; a ganglion, which may be regarded as a gigantic way-station, in which auditory and spinal tracts meet, and are continued brainward, through cerebello-cerebral fasciculi. It was not so very long ago supposed that the cerebellum as a "lower centre" was crowded out by the higher cerebrum in the ascending animal series, whereas the fact is that this ganglion is vastly larger and more intricate in higher animals than in lower ones, and shows an individuality in the type of its foliated arrangement, comparable to that adverted to in the case of the olivary nuclei.

It being thus evident on structural grounds that the ganglionic enlargements in which certain spinal tracts appear to terminate have an object, which could not be fulfilled if those tracts ran directly to the cortex, we must look to the other connections of such ganglionic masses for an explanation of that object. To take a hypothetical case. Suppose the cerebellum received fibres from the skin through the "sensory tracts" in the cord, and from the semicircular canals through the auditory nerve, and despatched another tract to the cerebrum; assuming that the direction of functional transmission were in all these tracts toward the cerebrum, there could be but one conclusion: that the cerebellum served to co-ordinate and fuse space sense perceptions from the skin, and such from the semicircular canals, and acted as an informing depot for the cerebrum; the latter is through its informant, which spares the cerebrum the task of co-ordinating these impressions into a united general space sense, enabled to guide motion in accordance with the latter.[1]

The probable object of the internodial or interrupting ganglia is the mediation of some functional combination. The manifold interruption of the tracts of sensation, as contrasted with the direct course of the tract of voluntary motion, hence appears as the anatomical expression of the fact that the motor impulse is a comparatively simple step, but that the building up of the contact and space senses which guide such motion to a skilful purpose is a far more intricate and laborious task, which is thrown on the centripetal tracts, and hence requires a greater anatomical complication.

I need but cite briefly a few facts recently observed by me in an interesting case[2] which justify the surmise above expressed, that certain tracts physiologically and anatomically regarded as centripetal really may convey functions centrifugally in a part of their course. An elderly gentleman, after a small hemorrhage in the pons, which caused unilateral ataxia of the opposite extremities, lived six years, during which time an intense secondary degeneration developed in the *descending* direction, and terminated after decussating in the opposite nuclei of the columns of Goll and Burdach, which were likewise atrophic. Now as far as secondary degenerations follow any law,[3] it is supposed that if a ganglion degenerates together with an appended tract, that both must belong to the same physiological system. The columns of Goll and the upper part of the columns of Burdach degenerate centripetally, that is, upward, or *toward* their nuclei. The diseased tract in my patient had degenerated centrifugally, that is, cordward, and hence from an opposite direction, also *toward* these nuclei. Here is an unquestionable instance in which two segments of the same tract—for the upper segment must be regarded as in part the cephalic continuation of the lower—degenerate toward an interpolated ganglion when diseased, justifying the assumption that functional impressions converge toward it, though not excluding the possibility of a continuous transmission brainward of sensory impressions[1] at the same time.

I have considered it necessary to make these introductory remarks, because to me the impression seems to prevail that all that is necessary to understand the anatomical part of the cerebral mechanism is the tracing of the centripetal tracts to the muscles in which they terminate, and the centrifugal ones to the cortical fields, from the peripheries, whose impressions they convey to them. This is important and essential, but it does not exhaust the duties of the anatomical psychologist, and is not even feasible in the case of many fasciculi. What I said some years ago[2] with regard to the functions of nerve-centres generally, "That day is past when it could be considered legitimate to refer every phenomenon provoked by an intracranial experiment to an altered activity of any single centre!" naturally applies also to the nerve-tracts whose connection with the nerve-centres is a factor in the function of the latter.

With these preliminary remarks, I have intended to pave the way for the understanding of the lemniscus: a nerve-tract of at least equal importance with that of the pyramids, an importance which is just being recognized, and which from its manifold, systemic, and topographical relations offers an opportunity for the discussion of many new or imperfectly understood features of isthmus anatomy.

II.—External and Gross Anatomy of the Lemniscus.

On the outer (lateral) face of the mesencephalon, that is, on the slope which intervenes between the *corpora quadrigemina* and the bulging *pes* of the cerebral peduncle of each side, there is a distinctly marked triangular field, known as the *lemniscus* or *lagueus*.

This is not merely a surface feature of the brain-isthmus (or axis), but the exposure of a great brain-tract, which in this particular area is uncovered by other nerve tissues, and elsewhere is deeply imbedded in the substance of the *thalamus* region, the *pons*, and passing through the *oblongata*, becomes intimately related with the ganglionic elements of the great centripetal columns of the cord, namely, the nuclei of the columns of Goll and Burdach, as well as the dentated body of the olive. Just as the columnar elevations of the oblongata, known as the pyramids, represent only a small segment of that great system, the will-tract, to which they have given the anatomical name of "pyramid-tract," so the surface area of the lemniscus indicates but an insignificant portion of the great tract which bears the same designation.

Halier[3] discovered the lemniscus, describing its situation and shape, but to Reil[4] is owing the credit of having recognized that the triangular field discovered by Haller is only the surface denudation of an important system of fibres. He found that it was not in connection with the pyramids, though some admixture of the fibres of the fillet and the pyramid was alleged by him, and traced it to the situation to-day known as the stratum of the fillet (Schleifenschicht). He later claimed that it passed between the olivary nuclei and the pyramids in the oblongata, and became indistinguishably fused with both of these bodies. Rosenthal undertook to correct this latter statement, which, as far as the pyramids are concerned, is partly true, for my own case demonstrated the existence

[1] The facts happen to justify this hypothesis, to some extent. As bearing on what the writer said about the possibility of tracts customarily regarded as centripetal conveying centrifugal functions, it may be well to refer to the fact that if Flechsig's suspicion, that the direct myelo-cerebellar tract is centrifugal, turn out to be well founded, that the cerebellum may exert a direct influence on a certain class of movements, without the intervention of the cerebrum at all. This would but increase the force of the remarks made in the text, as to the importance of the "interrupting" and "co-ordinating" stations. The above idea has been borrowed, with others, by Ranney.

[2] This case has been reported elsewhere, to be hereinafter referred to, when the questions involved will be more fully discussed.

[3] I question whether they do follow such law as invariably as some assume.

[1] Or of hitherto unsuspected centrifugal transmission cordward. The columns of Goll may occasionally degenerate downward or simultaneously with their nuclei: at least this seems to have been so in Sioli's case (Archiv f. Psychiatrie, xi., 3, p. 693). This surmise would offer the explanation of possible physiological transition for the case of some rodents, like the rat, in whom, according to Flechsig, the fibres of the true (?) pyramidal decussation enter the posterior columns.

[2] The Architecture of the Oblongata, N. Y. Medical Journal, September, 1881. It is refreshing to find this identical conception emanating from another writer in the same journal several years after. Unfortunately the context of his conclusion furnishes no hint as to the method by which he arrived at an opinion so similar in its phraseology to the writer's. It is in fact a disconnected plagiarized sentence, like another previously referred to as appropriated from the same source.

[3] Elementa IV., p. 175. According to Burdach.

[4] Reil's Archiv, ix., p. 149.

of degenerated fasciculi in the otherwise healthy pyramid, and these were connected with the degenerated interolivary field.

The discovery of Haller was ignored by the anatomists who described the mesencephalon after his time, and before that of Reil. Vicq d'Azyr,[1] whose plates are usually singularly true to nature, represents the lateral field of the mesencephalon as a uniform rounded surface, and neither designates nor describes the lemniscus, while Gall[2] gives an excellent illustration, particularly accurate as regards the deeply depressed acute apex, but does not refer to it (Plate XIII., under "30").

Burdach, who mainly follows Reil's description, gives an accurate account in his text, but his artist erroneously represents the fourth pair as arising from each lemniscus, instead of from the valvula (Plate IV.). The lateral aspect is very well represented in the fifth plate of the same work.

Reil recognized comparatively clearly that the lemniscus, in passing through the pons, is distinctly separated from the transverse fibres of the cerebellar system, and in many of the writings and illustrations of his day, it may be seen that the so-called "bundle from the pes to the tegmentum," described by Henle,[3] was considered, at least in its posterior division, a part of the lemniscus.

One of the sharpest lines of separation of nerve-tracts is the one which in the pons region separates the lemniscus and the transverse pons fibres. This line of separation was misinterpreted by the older anatomists. Vicq d'Azyr's artist, one of the most conscientious draughtsmen, has permitted his artistic interpretation to encroach on anatomical truth, more in this than in any other detail of encephalic anatomy. On Plate XXV. he makes a round nugget of the pons, completely encasing it in a whitish shell, of which the dorsal half is the bundle from the pes to the tegmentum, while the ventral portion represents the superficial transverse fibres of the pons. The joining portions are altogether imaginary. He apparently recognized the continuous tract of the above-mentioned bundle, but engraved it from memory, notes, or hasty sketches—he certainly had not the specimen before him—and confounded the posterior longitudinal fasciculus, the stratum intermedium, and the tracts from the mamillary body, duplicating them in one place so as to be entirely incomprehensible.

The bundle overlying the line of separation is very distinctly and correctly represented on Plate XII. of Gall's atlas.

The figure reference (85) reads: "Ligne de séparation entre les parties antérieures (ventral) et postérieures (dorsal) de la masse cérébrale ascendante," and evidently relates to the sharp line of demarcation which separates this fibre mass from the transverse pons fibres. The course of the tract as visible in sagittal sections is correctly represented as being between the *substantia nigra* (*Ganglion Soemmeringii*, E. C. S.), and the olivary region.' I have sections in my collection which are exact reproductions of this plate, a signal confirmation of the accuracy of Gall's delineations.

In order that the general reader may not become lost in the obscurity of the brain-axis terminology, I may be pardoned for digressing here to explain the meaning of some of the terms already used, and the topography of the parts with which we are about to deal.

The brain axis or isthmus is the continuation upward of the spinal cord. It is the common trunk (hence the German term "Hirnstamm" or brain trunk) from which the two cerebral hemispheres crop out like swollen ter-

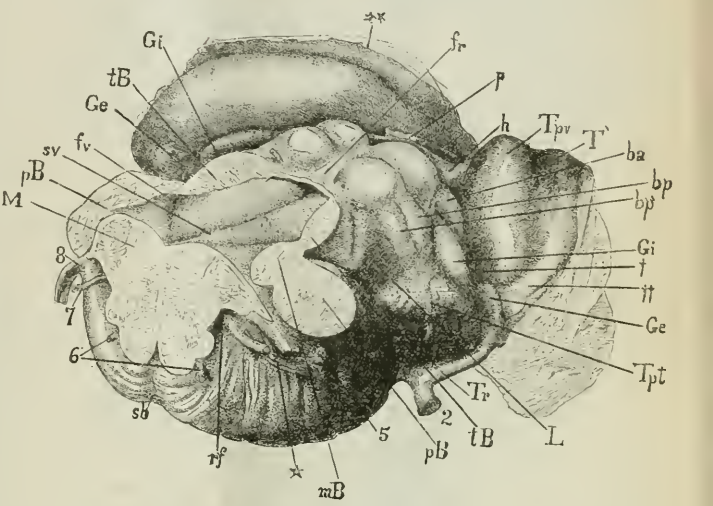

FIG. 1.—Brain Axis or Isthmus, with the Oblongata nearly entirely removed, by a sweep of the knife through the Acustic Striæ. *M* represents this cut surface, on which the contours of the raphé, olivary nuclei, pyramids, and restiform columns are faintly indicated. The isthmus is tilted in such a way that the lateral and superior (dorsal) faces are simultaneously visible; in other words, if the plane passing through both (ideal) retinal planes of the observer be regarded as vertical and corresponding to the page, the axis of the isthmus deviates from this plane forward 45°, and upward in the plane 27°. The following indicate the principal parts. A, of the oblongata: *M*, cut surface; 8, auditory nerve root. B, of the pons: *pB*, cut surface of *pontis brachium* (middle cerebellar peduncle); *mB*, ditto of *myelo-brachium* (posterior cerebellar peduncle); *tB*, *tB*, ditto of *tegmenta-brachium* (anterior cerebellar peduncle); those of both sides are connected by the divided *valvula*, of which *fr* indicates the *frenulum*. Between the cut edge of the oblongata section and the semicircular combined section of the cerebellar peduncles, the anterior half of the fourth ventricle is set like a picture in a frame; *sv* indicates the *median sulcus*, which anteriorly deepens into the aqueduct under *fr*, while *fv* indicates the fovea, from which a groove runs demarcating part of the auditory triangle. The other references are: 6, abducens (sixth) nerve roots; 7, ditto facial; 5, ditto trigeminus; *, the *tractus interradicularis pontis*, named and described by the author in the *Am. Jour. of Neur.*, May, 1884; *rf* the *recessus facialis*, named and described in the same number. C, of the mesencephalon: *fr*, *frenulum valvulæ*; *ba*, anti-brachium; *bp*, *bp'*, post brachium; *Gi*, *ganglion geniculatum internum*; *Tpt*, *tractus transversus pedunicularis* (crossing the pes). The corpora quadrigemina are so characteristic that they require no designation. D, of the thalamus segment: *Tpv*, pulvinar; *h*, *habenula*; *p*, cut surfaces of *epiphysis* (pineal gland); *Ge*, *ganglion geniculatum externum*, which is really only a thalamic nucleus; *Tr*, optic tract; 2, optic nerve; **, reflection of endyma of lateral ventricle; †, insinuation of branch of optic tract between *Gi* and thalamus to pass to *ba*; ††, singular tract-like elevation of thalamus surface, hitherto undescribed, and not equally well developed in all brains.

minal branches, while the cerebellum is an excrescence of the trunk itself.

In its general shape, excluding the inflections, it may be compared to an inverted truncated cone, for as we follow it up toward the cerebral hemispheres, it becomes wider and deeper, enlarging progressively in all directions. The lower small end is the spinal termination, the upper wide end is the cerebral or thalamo-crural end. The entire axis may be considered under the following four heads: 1. Thalamic division. 2. Mesencephalon (region of the corpora quadrigemina). 3. Pons. 4. Oblongata. In the main the thalamic division consists dorsally of two great flaring-out masses, separated by the third ventricle. Ventrally it includes the subthalamic region and that part of the crus which prepares to merge into the internal capsule.

The mesencephalon is marked dorsad by the four beautiful eminences of the corpora quadrigemina, ventrad by the symmetrical and cylindrical prominences of the

[1] Traité d'Anatomie et de Physiologie, 1786, tôme 1ere, Plates XXVII. and XIV.

[3] Anatomie des Menschen, iii., 1871.

[1] Respectively references 30 and *a* of the same plate.

crura (pes portion). The transverse section in adult man exhibits a black crescentic line on each side which sharply separates the crus proper (pes) from the dorsal part, which merges into the corpora quadrigemina and is known as the tegmentum. This black crescentic line is the *substantia nigra* of Soemmering. It constitutes the most important boundary line in the deep anatomy of the brain axis.

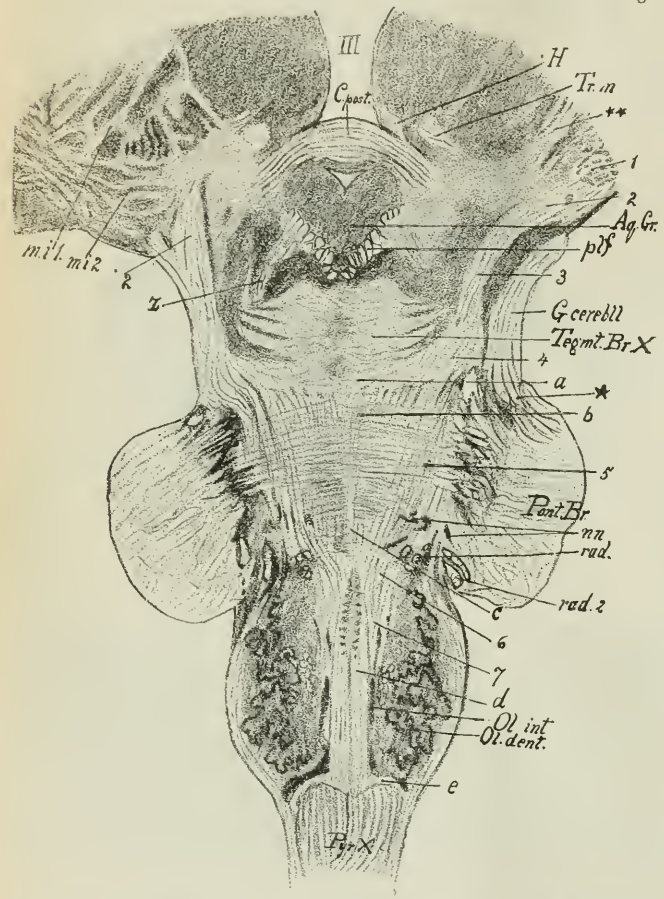

FIG. 2.—Section flat-wise, that is, parallel to the base of the brain axis, through the *Thalami*, *Mesencephalon*, *Pons*, and *Oblongata*, extending to the *Spinal Cord*. It dips a little lower on the right than on the left side, and to this the slight asymmetry of the figure is due. The following figure references relate to the thalamic and subthalamic regions: *H*, habenular tract; *Tr. m.*, **, *m. t.* 1, and *m. t.* 2, medullary laminæ of thalamus; *C. post.*, commissura posterior; *III.*, third ventricle. The following relate to the mesencephalon: *Aq. Gr.*, aqueduct gray matter; *pfs*, posterior longitudinal fasciculus of the tegmentum; *z.*, part of the descending trigeminous root; *G. cerebll.*, the direct tract from the cerebellum to the posterior part of the cerebrum, discovered by Gratiolet, confirmed by Flechsig, and which courses through the outer part of the *pes pedunculi*; *Tegmt. Br. X.*, decussation of tegmenta brachium or brachium conjunctivum, also known as Wernekiock's commissure. The following refer to the pons: *rad.* and *rad. 2*, auditory and facial nerve roots cut across; *nn*, nuclei of pons gray; *, cerebellar origin of *G. cerebll.*; *Pont. Br.*, *pontis brachium*, or middle peduncle of cerebellum divided across. The following relate to the oblongata: *Pyr. X.*, decussation of true pyramids; *Ol. dent.*, dentated or main part of olivary nucleus; *Ol. int.*, internal auxiliary part of same. The other references relate to the lemniscus tracts, and are explained in the text. The specimen was stained by carmine, being cut in my microtome from the brain axis of a Swede, whose brain I secured through the courtesy of Professor James L. Little. It was hardened in bichromate of potash.

The pons exhibits dorsad the upper half of the floor of the fourth ventricle. Ventrad a bridge of nerve-substance apparently jointing the cerebellar hemispheres.

If the beginner will conceive a conical piece of wood, whose base is turned upward, split by an axe, while a band is thrown around the middle of its length to prevent the split from extending through to the apex of the cone, he will have a crude idea of the relations of the pons as seen at the base of the brain. The two parts on each side of the split are the pedal crura; the split is the interpeduncular or intercrural depression; the belt is constituted by the bridging portion of the pons, below which the unsplit part represents the oblongata.

The pes and tegmentum are separated in the pons by the sharp line of separation alluded to in the historical introduction.

In the oblongata, it is impossible to make as clear a division of the tegmental and pedal part of the brain axis as in the pons and mesencephalon. The pyramids are the true representatives of the pes.

The exterior of the brain axis is sculptured into numerous eminences—some of them in very high relief—and depressions. Of the eminences, some, like the *tuber* cinereum of Rolando, the olives, and the clavæ, are due to the accumulation of gray matter beneath the surface at that point; others, like the pyramids, the restiform columns, the crura, are due to the prominence at certain points of the surface of the great nerve-tracts. It is to this class that the eminence, known as the lemniscus, belongs.

As represented in the figure L the elevation of the lemniscus is a flat triangular field, with one truncated and two sharp angles. Of the latter, one, the superior (dorsal), comes in contact with the superficial origin of the fourth pair of cranial nerves. The anterior corresponds to the (apparent) junction of the *crusta* and *post-brachium*.[1]

The posterior truncated angle is overlapped by the redundant growth of the pons. While the anterior side of the triangle—that is, the one connecting the superior and anterior angles—sinks below the post-brachium, the inferior side is in contact with the dorso-lateral edge of the crus, and the posterior (on which the light in the figure falls) rises in bold relief, cropping out over the *tegmenta brachium*.

These surface appearances indicate the actual relations of the lemniscus tract to some extent. It may be regarded as a flat band, which is dragged out of the substance of the pons to overlap the *tegmenta brachium*, to be overlapped itself by the crus and the *post-brachium*; in its known course it extends from the thalamus region to the lowest levels of the oblongata. Unlike the pyramid tract, which is a single united system of uniform physiological relations, the lemniscus tract includes a number of nerve-bundles having different destinations and different ganglionic connections. Indeed, with our increasing knowledge of this part of the cerebral projection system, it will, I think, become recognized that the including of all these bundles under one generic term is improper and misleading. One feature is found with all of them, that they are (in part, at least) related to functions regarded as centripetal and sensorial, as far as we may draw surmises from structure. The part

[1] Arm of the posterior pair of the corpora quadrigemina. In the figure an interesting variation is shown: this arm exhibits its two characteristic divisions (*bp* and *bp'*), and at the end of the pointer, *bp'*, the intumescence known as the *ganglion geniculatum mediale*.

of the brain axis, in which the lemniscus tracts are seen in their clearest relation, and where the various designations of authorities are most in accord, is exposed by a transverse section through the posterior pair of the corpora quadrigemina or a little behind this, through the *valvula*.[1] Typically each lemniscus stratum consists of an L-shaped area, so situated that the area of each lemniscus stratum touches the median (line) raphé with the free end of the horizontal branch, thus ⌊ ⌋. Even in sections which are inclined to the axis more or less, as in Figure 2, a similar appearance is noted. Here *a* on the right side represents the horizontal branch, and 2 on both sides, 3 and 4 on the right side, represent the vertical portion.

This figure indicates at the same time as much of the entire course of the lemniscus tracts as any one section can. It is seen to extend from above the pyramidal decussation at *e* between the olives at *d*, then spreading over an immense area, along 6, 5, 4, 3, 2, 1, to the thalami, gradually becoming more and more remote from the median raphé, while another detachment remains near to it, at *c*, *b*, and *a*. As in all sections of this character, the apparent continuity of the fibres is accidental, the various parts are intermingled somewhat; but as other sections and other methods of study show, all of them appertain to the lemniscus tract. Let us proceed to discuss these in detail.

(To be continued.)

SOME POINTS ON THE USE OF HEAT AND COLD IN THERAPEUTICS.[2]

By JAMES B. HUNTER, M.D.,
SURGEON TO THE WOMAN'S HOSPITAL, NEW YORK.

I AM well aware that the subject of the application of heat and cold in therapeutics is a very large and comprehensive one, and I shall attempt no more than to present a few points which have been suggested by my own experience.

The use of heat and cold, in some form, for the relief of disease is almost universal. There is hardly a disease known in which, at some stage, it is not deemed necessary to interfere with or modify the existing thermal conditions, the interference varying between the use of the actual cautery on the one hand and of ice or freezing mixtures on the other. Between these extremes the ways and means of modifying temperature are very numerous. The necessity for some interference is taken for granted. Some of the most advanced professional minds have for centuries past grappled with the problem of temperature as modified in disease—while every household has its favorite theories and maxims concerning the treatment of diseases and injuries by means involving a change of temperature.

Yet, notwithstanding the antiquity of what may be called the thermal method of treating disease, and its almost universal application in some form, there exists a surprising difference of opinion concerning the use of heat and cold, especially as to which of these powerful agents should be employed in any given case.

Professional opinion is assuming greater uniformity on this point with the advance of physiological science; but popular opinion, which often reflects the professional opinion of a former generation, differs very widely. But whether heat or cold is preferred, public opinion is always in favor of the generous use of one or the other. A gentleman of my acquaintance who was spending some weeks in a country region, chanced to sprain his ankle. He was carried helpless to the nearest farmhouse, where he was prescribed for by two experienced matrons. One insisted on placing the limb under a stream of cold water from the pump, and keeping it there for half an hour, assuring him that he would be able to walk the next day if her advice were followed. The other advised placing the injured limb in a pail of water nearly boiling hot, and keeping it *there* for half an hour, promising the same result on the morrow. Meanwhile a boy was despatched to the nearest village for medical aid. The doctor sent for was not at home, but his assistant visited the patient promptly, and endorsed the prescription of cold water, which was thoroughly carried out. On his return in the evening, the senior physician, thinking the patient a gentleman of some consequence, hastened to see him, examined the ankle carefully, and advised that very *hot* water should be applied during the whole night.

A similar difference of opinion is common both in the profession and out of it. Whether it be a sprained ankle, an inflamed knee-joint, a bruise, a wound, a burn, a fever, there is often a radical difference of opinion as to whether heat or cold will give the greatest relief or accomplish the most good. The explanation of this difference of opinion is probably to be found in the fact that many diseases and injuries require at different stages the use of both heat and cold, and that the indications for the use of either one are not always clear. In the earliest stages of inflammation the prompt abstraction of heat often suffices to abort or control the inflammatory process. After inflammatory changes have taken place, the application of heat to the same part may, by stimulating capillary and lymphatic action, hasten absorption and be eminently proper. In some cases this explanation does not apply, as in the use of both hot and cold water for the arrest of hemorrhage, or of hot and cold applications for the relief of neuralgia, regarding which there still exists some difference of opinion. It is safe to say that in no given case is it a matter of indifference whether heat is added or subtracted. The same difference of opinion exists, however, as to the use of some medicinal agents quite opposite in their effects.

But I must necessarily pass over or allude very briefly to many points which suggest themselves in connection with this subject.

I. I will first consider briefly some of the diseases in which the abstraction of heat, generally or locally, is demanded.

Typhoid fever, perhaps better than any other disease, illustrates the good effect of antipyretic treatment. Dr. G. L. Peabody, in a valuable statistical paper read before the County Medical Association, March 17, 1884, on the treatment of typhoid fever, says: "The effect of high temperature is very deleterious upon normal tissues, and its influence is distinctly evil in reference to the possible healing of intestinal ulcers." As the result of his own experience, and a careful examination of the records of the treatment of typhoid fever in seventeen large hospitals, in this city and in Europe, those of the British army and navy, and of our own army, Dr. Peabody emphatically endorses the use of cold water in the treatment of that disease. He shows the mortality to be only seven and one-fourth per cent. in a series of over eight thousand cases; and a series of two hundred and eleven cases in Dr. Brand's private practice all recovered under the antipyretic treatment. Dr. Peabody laments the difficulty of introducing the practice generally, the necessary appliances being cumbersome and expensive. The affusion of cold water he has not found satisfactory; the cold coil he considers unsuitable; and the cold bath the only really efficient method. Now, a cold bath in the immediate proximity of a patient sick with typhoid fever is not often obtainable. The patient may be sick in a country house, where bath-tubs are unknown; in a hotel, where they are fixed and remote from the patient's room. Even in a private house with all modern appliances it is not an easy matter to transfer a patient from a sick-bed to a bath-tub and back several times a day without a good deal of disturbance to the patient, and an abundance of physical help. I would therefore suggest as equally efficient and far more practicable the use of the well-known, but somewhat neglected Kibbee fever-cot, or something

[1] Valve of Vieussen's.

[2] Read before the Practitioners' Society of New York, October 3, 1884.

equivalent to it. This cot, which was first devised and used by Dr. Kibbee for the treatment of scarlet fever, during a severe epidemic of that disease, consists essentially of a common cot or frame on which is stretched strong canvas or other material sufficiently coarse or open to permit water to pass through it. Under this is placed a rubber sheet, to catch and convey the water to a pail placed at the foot of the bed. The patient lies comfortably on this bed, on a blanket and sheet, but of course without mattress. Such a bed can be improvised almost anywhere at a very small expense. I once made a very efficient one, in the country, with an old coffee bag; and I once used an ordinary wire mattress. Any cot covered with canvas may be made available as a water-cot by cutting a sufficient number of holes in the canvas. When it is necessary to apply the cold water, the covering of the patient is removed from the body (not from the extremities), which is enveloped in or covered by a sheet; upon this sheet warm or tepid water is poured gently from a pitcher or watering-pot; the temperature of the water is then gradually reduced until it is sufficiently cold. The stream is kept up for ten or fifteen minutes, a dry blanket is then thrown over the patient, and sleep generally follows.

Having had considerable experience in the use of this method of reducing the temperature in cases of peritonitis and septicæmia following operations, and some experience with it in typhoid fever, I know it to be very easily managed, to come within the skill of any intelligent nurse or attendant; and that by its means the temperature can be reduced to any desired point and maintained there. The apparatus is simple, it requires but a small quantity of water, it involves no movement of the patient, and occasions no shock whatever. I therefore believe it to be the best means available in all cases of fever where artificial reduction of the temperature is desirable. This method was adopted very successfully by Dr. Thomas, for peritonitis following ovariotomy, in 1876.

Next in point of efficiency, for the same purpose, I would class the wet pack, by which I mean a folded sheet, wrung out of tepid or cool water, and wrapped quickly around the patient's body. In this case cooling takes place partly as a result of evaporation. If the attendants are industrious much may be accomplished by the use of towels wrung out of cold water placed upon the body and limbs, and frequently changed. Least useful of all, though very grateful to the patient, is sponging with cold water. If done often enough some heat is abstracted, and if alcohol is used with the water evaporation aids in cooling.

Where it is necessary to effect a local reduction of temperature, there are better means than the fever-cot. In threatening peritonitis after laparotomy, for instance, the use of a coil of lead or rubber tubing, through which water of any temperature may be continuously passed, affords a perfectly simple and efficient means of accomplishing the purpose desired.

M. Galante, of Paris, in 1852, devised a rubber apparatus for continuous irrigation of the eye. Dr. Petitgand, of Paris, had manufactured for him an apparatus of rubber tubing for this purpose in 1859; and in 1866 he published a description of a head-cap made of rubber tubing for the use of cold water, and a *sachet*, a flat coil of rubber tubing precisely similar to the abdominal coil now in use. In 1879 Dr. Dumontpallier published a description of a series of tubular covers and mattresses, by the use of which, according to experiment, he claimed to be able to accomplish much more rapid and uniform refrigeration in typhoid, varioloid, and other fevers, than could be accomplished by the cold baths of Brand.

The use of the head coil of lead or rubber is now very general; and the abdominal coil is likewise becoming popular. Nothing can be simpler or less disturbing to the patient than the use of the abdominal coil, and in incipient peritonitis nothing that I am aware of is so efficient. The application of the rubber coil to this particular class of cases was suggested by Dr. A. B. Townsend, in the Woman's Hospital, in 1881. The coil is applied directly to the skin, or a thin towel is interposed. A bandage is then placed around the body to keep the coil in place; a pail of water, containing a lump of ice, stands on a table near the head of the bed, and a pail under the bed receives the water as it passes through. At the latter extremity, where the water escapes, there is a stop-cock by which the flow may be nicely regulated or entirely stopped, as may be rendered necessary by the temperature of the patient, as shown by a thermometer placed in the axilla from time to time. Unless the apparatus should be irksome to the patient, which is seldom the case, it is not necessary to remove it as long as there is any likelihood that it may be required. By simply opening the stop-cock the flow of water begins, and the cooling process may be stopped or resumed without waking a sleeping patient.

I have used in the manner just described both the rubber coil and the coil of fine leaden tube known as Leiter's coil. The latter have not been generally in the market, or I think they would have taken the place of the rubber in many cases. They are not so heavy, when full of water, as the rubber coil; they are not liable to become dirty, and have not the unpleasant odor of rubber. They are more durable and less expensive. They are not more liable to become clogged with dirt, if the precaution is taken to envelope the receiving end of the tube in a piece of gauze or coarse muslin, which should be done in all cases. With this precaution, and one nurse of ordinary intelligence, I have sometimes kept the leaden apparatus in use for three days and nights without a moment's interruption. One advantage of the metal coil is that it requires less water, and that it is seldom necessary to use ice. Being a much better conductor than the rubber, the use of water at a temperature of 45° or 50° is quite sufficient. I consider these appliances of the greatest possible value where inflammation is threatened, and most important means of limiting inflammation when it has developed. In case of bad operations, where there is every reason to expect peritonitis, I have the coil placed upon the patient immediately after she is put to bed, so that it may be ready for use at any moment. In ordinary cases I wait until the temperature rises above 100° in the axilla.

In the method spoken of the object of course is to reduce bodily temperature; but cold is sometimes used as a means of impressing the nervous system. Chapman's ice-bags act on this principle, and have been found useful in many nervous disorders. My own experience with these ice-bags has been limited chiefly to their application in cases of painful and scanty menstruation. In a certain class of cases the application, for half an hour at a time, of a bag of crushed ice to the region of the lumbar vertebræ and sacrum, has the effect of promoting the menstrual flow. Applied to the dorsal vertebræ, in an anæmic patient with cold extremities, the tendency of the ice-bag is to equalize the circulation and promote warmth throughout the whole body.

Friction with ice is employed in frost-bite. The late Dr. Peace, of Philadelphia, claimed to have had excellent results, in a cholera epidemic through which he passed in Europe, from vigorous friction of the limbs and body with lumps of ice. Where it is necessary to stimulate the nervous system, the alternate application to the spine of a flat brick of ice, and a very hot iron, protected by flannel, is sometimes very effectual.

I shall merely allude to the popular and time-honored belief in the styptic effects of cold; to the undoubted value of cold for the relief of pain in burns; and to the efficacy of ice-cold applications in the causalgia consequent on injuries of the nerves from gunshot wounds.

II. Of the manifold forms in which heat is employed as a remedy for pain and disease, I shall dwell on a few only of the most striking, at the risk, as in what I have

said of cold, of telling a thrice-told tale. For the arrest of hemorrhage a high degree of heat has been long in vogue. The hot iron has held its place as a styptic probably for many centuries; and the cautery in some form is still constantly employed for the same purpose. The use of a moderate degree of heat for the arrest of a more general hemorrhage is of recent origin. To Dr. Emmet we are indebted for having demonstrated the hæmostatic properties of hot water. Where ice and cold water were formerly used, hot water is now found to answer a better purpose. In hemorrhage from the uterus after miscarriage, or after removal of a fibroid, or from any other cause, injections of very hot water at the same time arrest the hemorrhage and promote contraction of that organ. This is one of the many applications of heat where experience has placed its value beyond a doubt. For the arrest of hemorrhage from an exposed surface, towels dipped in very hot water and pressed firmly on the bleeding part for a few minutes will generally act much more promptly and permanently than cold water used in the same way. A stream of very hot water thrown with a syringe into any bleeding cavity, if there are no vessels of large size, will generally prevent further flow of blood. The remarkably good effect of hot water for this purpose, during and after operations, may be witnessed every day in many of our hospitals. One great advantage, if there were no other, in favor of the use of hot water for exposed surfaces, or for the uterine cavity, is that the process of boiling is purifying, and one of the most reliable means of destroying organic matter, bacteria, or other minute organisms which are believed to play so destructive a part in the human body. A higher temperature than that of boiling water has been proven to destroy some germs which escape simple boiling. For that reason I always, if practicable, employ for antiseptic solutions and for surgical purposes water from the boiler of a steam-engine, which has usually been heated to about 250°.

The beneficial effects of vaginal injections of hot water are now generally appreciated, and form an important part of every-day gynecological treatment. So much depends upon the manner in which these injections are given, that I will venture to describe the method I consider the best. The patient should lie flat upon a bed or sofa, with the hips raised upon a broad bed-pan, capable of holding four or five quarts of water. With a Davidson's syringe, having a hard-rubber nozzle not perforated at the extremity, a stream of water as hot as can be borne, from 100° to 110°, should be gently thrown into the vagina for ten or fifteen minutes, or until three or four quarts of water have been used. The Davidson's syringe is better than the fountain; a bed-pan without pipes or openings or stop-cocks is better than a more complicated apparatus. It is difficult to keep the simplest vessel of the kind clean, and almost impossible some of the more complicated ones.

The effect of injections given thus night and morning is often quite surprising. The hot, swollen, congested mucous membrane or the vagina assumes a normal appearance, the offensive discharge ceases, the extreme tenderness disappears, the engorged cervix softens and diminishes in size, there is a marked general improvement without any medication whatever, and the patient has made a great step toward getting well. I make a rule of questioning a patient in detail as to whether she has taken her injection thoroughly. A pint or two of lukewarm water feebly thrown into the vagina, while the patient is sitting over a basin or other vessel, is often considered sufficient and expected to yield good results; but such a use of hot water for this purpose resembles the proper injection only "as the mist resembles the rain," and leads only to disappointment. In pelvic cellulitis the persistent use of hot water hastens the absorption of the plastic exudation and shortens the duration of the disease.

One of the applications of heat that may appear paradoxical, in view of what has been said of refrigeration in peritonitis, is the very common custom of covering the abdomen with hot poultices for the relief of the same disease. There is really nothing antagonistic in this. The object of the hot application is not to augment the heat of the parts, for there is already too much heat and congestion, but what the poultices and hot fomentations do is to stimulate the capillary circulation and that of the underlying lymphatics, and thus relieve the engorgement of organs more remote. Such applications are grateful to the patient, and that they often do much good there can be no doubt. I think that warm applications are useful, chiefly in the forms of peritonitis that develop rather insidiously, with pain over a large area. Where the disease is local, and especially of traumatic origin, I should prefer cooling measures from the beginning. There is nothing at all inconsistent in the use of both hot and cold applications at different stages of the same disease, and in the same case.

It would carry me beyond my limits even to enumerate all the familiar applications of heat in therapeutics. The value as a counter-irritant of Paquelin's cautery, used at a white heat and brushed lightly over the surface, is generally acknowledged. The application of heat over the region of the heart as a stimulant in threatening collapse, is often found of value, and I have utilized the rubber coil for that purpose; the medicinal use of hot water as a beverage reminds us that there is fashion in everything. More than one hundred and fifty years ago Le Sage, in his immortal "Dr. Sagrado," ridiculed the routine use of hot water and bleeding. The hot water has come back to us; the bleeding, as its adjunct, may follow.

In conclusion, I would suggest that as we have in heat and cold agents powerful enough to destroy life, and under proper control capable of modifying all its functions, they should always be prescribed with a definite object and used in a definite manner. As their use is often intrusted to those who know nothing of the principles on which they act, and who are influenced by custom or prejudice, the physician should take suitable opportunities of imparting some general information to his patients as to the most rational means of employing remedies that, however or by whomsoever prescribed, will always be considered the property of the household, and within the province of domestic practice.

A RARE FORM OF LOBAR PNEUMONIA—TUBERCULOUS CROUPOUS LOBAR PNEUMONIA.

By FRANCIS P. KINNICUTT, M.D.,
PHYSICIAN TO ST LUKE'S HOSPITAL, NEW YORK.

F. H——, male, aged thirty-three, single, native of England, was admitted to my service in St. Luke's Hospital March 6, 1884. Family history not obtainable. The patient states that he has never suffered from any pulmonary affection. Eighteen months ago he was injured in a railway accident, and has been troubled since that time with a continuous "to and-fro movement of his head," which he has been told ceases during sleep. During this period he has lost flesh. He has had no cough or hemorrhage, and was apparently in good health until three days before admission to the hospital, when he had several sharp chills, followed by cough and a thickish expectoration and apparently fever. On admission to hospital patient was fairly well nourished; temperature, 104°; pulse, 100; respirations, 38. There was cough; the sputa were viscid, but not rusty. There was a constant rhythmical to-and-fro movement of the head, which ceased during sleep. Examination of the chest showed dulness, with feeble respiratory murmur and abundant fine inspiratory crepitation over the infra-clavicular region and upper portion of the mammary of the right side. The urine was acid, specific gravity 1.028, and was free from albumen and sugar. The chest was very carefully examined by me daily. The physical signs of consolidation of the entire

upper lobe of the right lung (marked dulness, bronchial respiration, and bronchophony) rapidly supervened; there was continuous pyrexia; the pulse-respiration ratio of one to a little less than three was maintained. Until the eighth or ninth day of the patient's illness the clinical course of the disease in all respects corresponded with an ordinary attack of croupous lobar pneumonia, and was so regarded by me. Resolution, however, did not occur at the customary period; there was, on the contrary, from the ninth day after admission to hospital until death, a gradually increasing pyrexia, pulse, and respiratory rate. Examination of the chest, moreover, revealed a very rapidly developing disintegration of lung tissue at different points in the affected area. On the thirteenth day there were the physical signs of a small cavity in the upper portion of the consolidated lobe, corresponding to the site at which the largest excavation was found after death

During the last days of life slight hæmoptyses occurred, and there was effusion into the right pleural cavity. A similar case had never before been observed by me, but from the clinical course of the disease I finally was led to believe, and expressed the opinion, that the morbid process might well be expressed by the term tuberculous croupous lobar pneumonia. The patient died on the sixteenth day after admission to hospital, on the nineteenth from the first symptoms of acute illness, with the signs of general pulmonary œdema and heart-failure.[1]

The autopsy was made by Dr. Ferguson in my presence. The morbid changes were confined to the brain, the spleen, and the lungs. There was marked atrophy of the convolutions over the vertex. The spleen was large and soft. The right pleural cavity contained about forty ounces of semi-purulent fluid; the pulmonary pleura was covered with recent fibrin. The left lung was intensely congested and œdematous; the entire upper lobe of the right lung was hepatized. On section the solidified portion appeared dry, smooth, and grayish in color and homogeneous in consistency throughout. The cut surface did not present the granular appearance of gray hepatization, and the edge of the knife carried over it did not remove the alveolar contents. Numerous miliary tubercles could be distinguished at the periphery of the consolidation. The middle lobe and the upper portion of the lower lobe contained numerous miliary tubercles. There were several small cavities in the consolidated portion, varying in size from that of a pea to a walnut, partially filled with material not completely disintegrated. In sections, the alveolar walls were seen to be slightly thickened and the alveoli to be distended with pus, a small amount of fibrin, granular material and epithelial cells similar in appearance to those lining the alveolar walls in the normal state. The alveolar contents in places had undergone cheesy degeneration. These areas of cheesy degeneration, which were numerous throughout the consolidated portion of the lung, were limited by zones of small round cells of inflammatory origin. In some of the caseous areas the alveolar septa were still preserved, but very generally they had disappeared in these areas, a fusion of many alveoli having occurred. In the neighborhood of the solidified portion there were numerous miliary tubercles and tuberculous masses with broken-down centres; in both, giant cells were well developed and abundant. In the interstitial tissue of the lung surrounding the tuberculous masses numerous small cells, both round and fusiform, were seen. Tubercles were not found in the other organs.

The pathological changes above described would seem to justify the application of the term tuberculous croupous lobar pneumonia to the morbid process. An apparently similar morbid process has been described by pathologists, but I have been unable to find *any clinical record* of such cases, with the exception of a general reference to them by Rindfleisch and a very brief report of two cases communicated to the French Academy of Medicine, December 4, 1883, by Professor Sée, under the title of "Phthisis in the Form of Lobar Pneumonia." I give the latter as reported in *Le Progrès Médical* of December 8, 1883:

Case I.—A young man, nineteen years of age, a hospital patient, was seized on September 13th with a well-marked attack of simple pneumonia, which involved the upper two-thirds of the right lung. At the end of the ninth day, defervescence not having taken place, the sputa were examined and bacilli in great numbers discovered. Early in October all the signs of an excavation became apparent.

Case II.—A patient in the same hospital ward presented all the signs of a simple pneumonia, which, however, did not undergo resolution. The sputa were twice examined, revealing only ordinary microbes in great numbers. A third examination established the presence of a small number of tubercle bacilli. Shortly afterward the local signs confirmed the diagnosis.

Rindfleisch,[2] under the head of "Cheesy Lobar Pneumonia," describes a form of desquamative pneumonia (Buhl) which occurs as a diffuse inflammation of an entire lobe affected by tuberculosis. "Usually the earlier stages of the disease have already passed by at the apex of the lung and cavities have formed, when a sudden attack of cheesy pneumonia occurs and involves at once the rest of the upper lobe. This usually happens with an acute exacerbation of all the clinical symptoms, the fever, dyspnœa, and rapid pulse, so that the impression is given of an intercurrent croupous lobar pneumonia, and the first glance at the lungs might seem to confirm this opinion, for, as Virchow has shown, there are very often in the alveoli plugs of real fibrinous exudation, so that the section of the lung looks granular. But the distinction lies in the infiltration of the alveolar walls, a condition very slightly developed in croupous pneumonia."

I prefer to regard the morbid process observed in my own case, and which has been carefully described, as an example of an intercurrent *croupous pneumonia*, from the presence in the alveoli of the usual products of such an inflammation—*e.g.*, pus and fibrin—which Buhl[3] insists are *never present* in the desquamative pneumonia first described by him. The implication of the alveolar walls and the presence of only a small amount of fibrin among the alveolar contents I shall again refer to.

The question of the probable period of the development of tubercles in the above case is certainly an open one. Personally, I am inclined to believe that a slight deposition of tubercles occurred at some time previous to the beginning of the patient's acute illness, but that little or no constitutional disturbance was produced thereby. The history of the patient, the clinical course of the acute disease as observed by me, and finally the post-mortem appearances, would seem to justify the opinion that on the date of the recorded chills a true croupous pneumonia was developed in the tuberculous lobe of the lung; that the pneumonic process furnished suitable soil for a very rapid and abundant development of the bacilli tuberculosis; that there was a consequent equally rapid degeneration of the tubercles of older date, and also of the pneumonic products. The objection to considering the pneumonic process a croupous one on account of the serious involvement of the alveolar walls, may be met by the argument that such an implication is believed by many pathologists to occur in cases of croupous pneumonia where resolution is delayed. The presence of only a small amount of fibrin among the alveolar contents may be explained in a similar manner; degenerative changes are to be expected where life is prolonged to the nineteenth day from the beginning of the attack.

[1] The sputa were not examined until the fourteenth day; two specimens were then examined, but tubercle bacilli were not found. On the fifteenth and sixteenth days the sputa were so scanty that specimens could not be obtained for examination.

MORPHIA IN CARDIAC DISEASE.

By BENJAMIN EDSON, M.D.,

BROOKLYN, N. Y.

THE following case seems to have some bearing upon the use of morphia in one form of disease of the heart.

C. R——, fifty-six years of age, Scotchman, merchant, called at my office early in November, 1883, complaining of a troublesome cough and shortness of breath on exertion. He attributed his trouble to "catching cold" from exposure. As he was in great haste I prescribed a cough mixture without making thorough investigation.

A few days later he called again. His cough was no better, and his respiration so much more difficult that he could not lie down to sleep. When I proposed an examination, he slapped his hand upon his chest, saying: "There is nothing the matter with me here, sir: I'm as sound as a dollar." I found, however, that he had mitral regurgitation with marked dilatation of the heart. The cause of the cough and dyspnœa was but too apparent. The kidneys were not affected, and as yet there was no œdema. A few days later the legs began to swell. I advised him to keep strictly quiet, and at the same time put him upon such treatment as seemed best calculated to give relief. I found it difficult to convince him of the grave nature of his disease, and being of a nervous, active temperament, he considered it a great hardship not to be permitted to attend to his daily business in New York. Finally I persuaded him to consult Dr. Armor, who confirmed my diagnosis and approved the treatment, which "must be palliative and on general principles."

For the next two or three weeks he continued fairly comfortable, the œdema moderate, but he was able to sleep only as he reclined in his chair. He was very irritable, and urgently called for something that would enable him to sleep *in bed*. I did not feel warranted in granting this request, but still he insisted that he must have some good sleep. Finally, through the persuasion of a relative, he was induced to call in a distinguished homœopathic physician, who acceded to his request and gave him sufficient morphia to enable him to sleep several hours in bed. But on waking and attempting to rise he was seized with dyspnœa that nearly terminated his life. By vigorous efforts on the part of his attendants he eventually rallied somewhat, but soon after he suddenly fell back and expired.

I have considered that death in this case was due to the morphia used. It may have been only indirectly the cause, by permitting the patient to assume the recumbent position, rising from which produced over-distention or overwhelming of the weakened heart-structure. Morphia may have contributed to the paralysis. Bartholow ("Materia Medica," 5th ed., p. 524) says of lethal doses of morphia, that "in some instances very sudden death ensues from paralysis of the heart." How large the dose required to produce this untoward result obviously depends much upon the condition of the heart. What in health might be but a medicinal dose of morphia, in case of dilatation, with muscular walls greatly weakened and nerve-distribution disturbed, might readily prove to be a lethal or paralyzing dose. Thus in this case it is not improbable that both these factors conduced to the sudden death of the patient.

This man had never had rheumatism, and previous to this illness there had never been any suspicion of cardiac trouble.

In looking back over this case there arises a question which leads to speculation, and which may not be wholly devoid of interest. In the summer of 1880, through some business complications, this man had a period of very great mental depression. It took the form of marked pathophobia. He was fearful that he would drop down dead, and that his body would be unrecognized and sent to the morgue, so he was very particular to keep in every pocket papers bearing his name and address, with minute directions as to what should be done in case of the event he so much feared. Scores of times daily he took out these papers and examined them to reassure himself that, if he did drop dead, his body could be properly identified. On one occasion, being up-town in New York, the "feeling" came over him that he never could get back to his store alive. His evil genius told him that he must not ride, and he had not the power to walk. In this dilemma it was finally revealed to him that he could perchance *run* back. This he did, by short runs between lamp-posts and awning-posts, to each of which he would cling while screwing up courage to make a bold run for the next goal. In this way he finally reached his store, out of breath and reeking with perspiration.

While narrating these and many other freaks of his malady equally ridiculous, he remarked, "You may laugh at them; I do now; but when the incubus is upon me I am a coward, a victim of my fancies." After a few weeks his business troubles passed away, and with them his morbid fear of death.

There is a possibility—indeed, is there not a strong probability?—that at this time there was actual heart-trouble. If so, whether it stood in the relation of cause or of consequence is of course mere speculation. Is pathophobia, with the kindred affections, agoraphobia, etc., simply a functional derangement—a neurosis—or may it not be associated with and possibly dependent upon actual pathological conditions?

Reports of Hospitals.

COOK COUNTY HOSPITAL, CHICAGO, ILL.

CASE OF CONGENITAL DIAPHRAGMATIC HERNIA.

REPORTED BY M. L. HARRIS, M.D., HOUSE PHYSICIAN.

E. C——, male, aged thirty-four, laborer, was received into the hospital November 15, 1883, under the care of Dr. F. Henrotin, attending physician.

On admission the patient was much prostrated and suffered from intense dyspnœa; hence no accurate account of his history was elicited. He said that he had usually enjoyed good health, and that this was his first acute illness. The case was found to be one of acute croupous pneumonia affecting the lower lobe of the right lung and complicated with an acute pleurisy of the same side. November 17th the patient died suddenly and unexpectedly.

The autopsy was held forty-eight hours after death by Dr. W. T. Belfield, pathologist to the hospital.

Body of spare build, the abdomen markedly depressed. After the usual incision from chin to pubes and removal of the sternum, the appearance represented in Fig. . was exhibited. The heart was in about the usual position, the apex a trifle nearer the sternum than normal. The right pleural cavity contained some recently coagulated lymph. The inferior and middle lobes of the right lung exhibited gray hepatization; the lower portion of the upper lobe showed red hepatization; the upper portion of this lobe was quite œdematous.

The left pleural cavity contained, besides the left lung, the stomach, nearly all of the small intestine, part of the colon, and half of the pancreas. The lung, eight inches in length, one to two inches in thickness, and two to three inches in breadth, was crowded into the anterior and upper portion of the left chest, resting against the mediastinum. It appeared to consist chiefly of the upper lobe, which, with the exception of a few cheesy nodules in the apex and some slight œdema, was fairly normal, crepitating well and floating upon water. The inferior lobe was crowded into a small firm mass which contained no air and sank in water.

The abdominal cavity was shallow, containing only

the liver, kidneys, spleen, a small portion of the ileum and ascending colon, and the descending colon. The liver was slightly enlarged and fatty; the anterior border of the right lobe extended downward four fingers'-breadth below the margin of the ribs, its deep position being due not to an increase in size but to a tipping forward and downward of the organ. The kidneys and spleen occupied their normal positions respectively and appeared healthy.

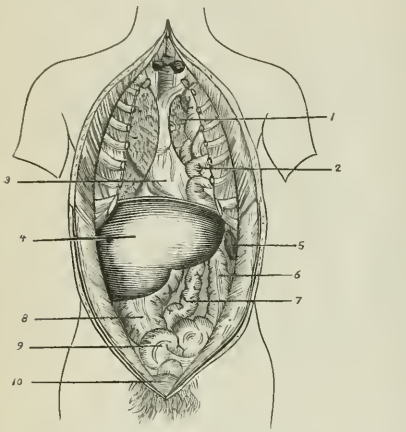

FIG. 1.—1, Left lung; 2, convolution of small intestine; 3, heart in sac; 4, liver; 5, spleen; 6, descending colon; 7, lower end of ileum; 8, cœcum; 9, sigmoid flexure; 10, bladder

The diaphragm presented a single large opening occupying its central and posterior portion, through which the various organs—inferior vena cava, aorta, thoracic duct, portal vein, small and large intestine, pancreas, superior mesenteric artery, etc.—passed to or from the thorax. This foramen was large enough to permit the

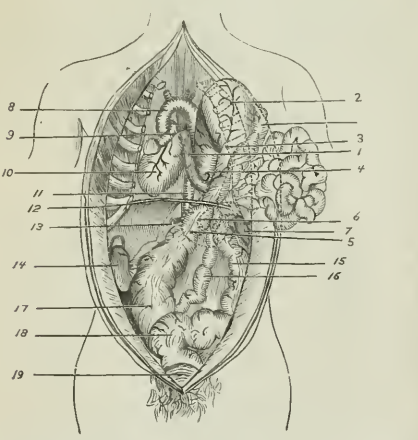

FIG. 2.—1, Œsophagus; 2, stomach; 3, pylorus; 4, cardia; 5, duodenum (dotted line); 6, pancreas (dotted line); 7, spleen; 8, arch of aorta; 9, pulmonary artery; 10, heart (drawn to right); 11, descending aorta; 12, diaphragm; 13, cut end of portal vein; 14, kidney; 15, descending colon; 16, ileum; 17, cœcum; 18, sigmoid flexure; 19, bladder.

passage of the closed fist. The left border of the right crus arched to the left, forming the free margin of the foramen; this was round and smooth and attached to the head of the twelfth rib and to the base of the transverse process of the twelfth dorsal vertebra. There was no left crus. The course and relations of the alimentary canal are shown in Fig. 2. Here the lungs and liver have been removed, the heart drawn to the right and the small intestine to the left, the ribs represented by the dotted lines.

The œsophagus passed behind the arch of the aorta, along the anterior and right side of the descending aorta, until it reached the eighth dorsal vertebra, where it passed in front of the aorta, suddenly turned vertically upward, and after a course of about two inches entered the cardiac extremity of the stomach. The stomach itself extended from this point upward to the apex of the thoracic cavity, then curved forward and downward, so that the greater curvature looked backward and upward, the lesser forward and downward. The duodenum commenced opposite the third intercostal space in front, passed down through the opening in the diaphragm into the abdomen, making a loop about eight inches in the abdominal cavity, in which lay the head of the pancreas; thence it passed back through the opening into the thorax. The remainder of the small intestine lay within the thoracic cavity, with the exception of about twelve inches of the inferior extremity of the ileum, which passed through the opening in the diaphragm into the abdomen toward the right iliac region, where it joined the cœcum, the latter occupying nearly its normal position.

The ascending colon passed directly into the thorax in front of the duodenum; the transverse extended along the left side of the stomach and entered the abdomen again; the descending colon occupied nearly its normal position. The rectum descended along the centre of the sacrum.

The pancreas lay directly in the opening, half within the abdomen and half within the thorax. The cœliac axis and mesenteric arteries were given off at their usual site. The gastric branch of the former and the superior mesenteric passed upward into the thorax, the splenic and hepatic branches directly to their respective organs. The portal vein descended through the opening to the liver. The genito-urinary tract was normal.

ST. CATHERINE'S HOSPITAL, BROOKLYN, N. Y.

CASE OF RUPTURE OF THE DIAPHRAGM.

REPORTED BY JAMES L. KORTRIGHT, M.D., CURATOR.

SIMON S——, fifty-eight years of age; German. Patient fell or sprang from the top of a three-story building. He alighted upon his feet and immediately fell prone with great force. He died three minutes after admission, and half an hour after the receipt of the injury. At the autopsy there was found a contusion in the frontal region without fracture of the skull or injury to the brain; a compound Colles' fracture at left wrist; a simple fracture at lower third of right femur; a simple fracture of the neck of the left femur; fractures of the costal cartilages of third and fourth ribs on the right side, and of the fourth, fifth, and sixth ribs on the left side. There was a large rent three inches in length across the muscular fibres of the left side of the diaphragm half an inch from their insertion into the central tendon. Through this rent there was a hernia of the entire stomach and transverse colon with the greater omentum. The stomach was distended with food and contused on its anterior wall. The heart was displaced to the median line, and stood vertically. Has any one ever seen a similar injury or known of a case where the abdominal viscera were driven through the diaphragm?

A SUCCESSFUL WOMAN PHYSICIAN.—*L'Union Médicale* gives an account of the career of a Parisian doctress who, after her school and hospital experience, went to Turkey, and after many adventures was made physician to a prince's harem, on a salary of 100,000 to 150,000 francs a year. This was "the bouquet of her adventurous existence." She subsequently lost this position but made amends by making a marriage *de haute convenance*.

Progress of Medical Science.

Removal of a Foreign Body from the Knee.—M. Boudet relates the case of a child who inserted a threaded needle into the knee at the internal border of the patella. An attempt to extract the needle by pulling on the thread resulted only in breaking the latter. An incision was then made, and although the needle could be easily felt in the tissues it could not be removed. It was finally proposed to place the child in the same position it occupied when the object was introduced. This was done and the needle was extracted with ease. Ambroise Paré practised a similar manœuvre when the King of Navarre was wounded by a ball in the shoulder at the siege of Rouen. The other surgeons having failed in their efforts to extract the bullet, Paré advised the illustrious patient to assume the same position in which he was at the time of receiving the wound. He did so, and the removal of the foreign body was accomplished with facility.—*Revue Médicale*, No. 32, 1884.

Treatment of Ozœna.—The following is the formula employed by M. Vidal at the Hôpital St. Louis, in the treatment of ozœna (*Journal de Médecine et de Chirurgie Pratiques*, August, 1884): Solution of chloride of zinc (5 per cent.), 1 ounce; boracic acid, 15 grains; water, 28 ounces; ammonia, q. s. to neutralize the fluid. A little of this solution is snuffed up into the nostrils several times a day. M. Gorecki employs for the same purpose, and in the same way, a warm saturated solution of boracic acid. By means of one or other of these preparations the fetid odor may be destroyed, in most cases, within a few days.

Encephalic Bellows Murmur in Children.—This sound, when it exists, is intermittent and isochronous with the cerebral pulsations. It is often perceptible over the anterior fontanelle only. According to Dr. Jurasq, this phenomenon is of no diagnostic value, but occurs at any time between the third month and the sixth year of life. The sound seems to be produced in the carotid canal or in the foramen spinale. These foramina vary greatly in diameter in children, and the bruit results from a disproportion between the calibre of the osseous openings and that of the internal carotid or middle meningeal arteries which traverse them.—*Revue Médicale*, August 30, 1884.

Clitrophobia.—By this term is understood a disturbance of the cerebral functions, somewhat similar to agoraphobia. The subjects of this affection have a horror of being in any enclosed place. When shut up in a room they experience a sensation of heat in the head, the arteries of the temples beat forcibly, they become furious and make frantic attempts to open the door or to leap from the window. Clitrophobia may exist as a pure monomania unaccompanied by any other delirious manifestations, or it may occur in connection with other psychological disturbances. It is a rare condition, and the prognosis should, in every case, be a reserved one. —*Revue Médicale*, No. 35, 1884.

Inhalation of the Vapor of Glycerine for Cough. —Professor Trastor employs with great benefit the vapor of glycerine for the alleviation of a fatiguing or painful cough. A couple of ounces of glycerine are put in a porcelain dish and evaporated over an alcohol lamp. A large quantity of vapor is thus given off which is inhaled with great relief by patients, especially consumptives who are troubled with a harassing cough.—*Revue Médicale*, August 30, 1884.

Ecchymosis of Nervous Origin.—In an interesting paper published in the *Revue de Médecine* of August 10, 1884, Dr. Keller relates a number of cases observed by him of ecchymosis occurring, without the intervention of traumatism, in nervous subjects. He came to the conclusion that, as in similar cases stated by Straus to occur in locomotor ataxia, the ecchymoses were directly dependent upon the abnormal condition of the nervous system in these patients, and this view was strengthened by the fact that the spots appeared less frequently in proportion as improvement occurred in the nervous condition. The patients were all women, and their condition varied from simple nervousness to hysteria and melancholia. Some were also of a rheumatic diathesis. Dr. Billod informed the author that he had observed spots of ecchymosis on the dead bodies of persons who had suffered from melancholia. This phenomenon of the spontaneous occurrence of ecchymosis in nervous women is a fact possibly of some importance in a medico-legal point of view.

Gummy Tumor of the Tongue occurring Forty-three Years after Infection.—Dr. Pellizzari relates the case of a man, sixty-five years of age, who in 1840 had a chancre, followed by pains in the head and bones, an eruption of the skin, and mucous patches in the mouth. He was treated with iodides and mercury, and was apparently cured. He married in 1855, had four healthy children, and enjoyed excellent health up to November, 1883. At that time a hard nodule appeared on the left side of the tongue anteriorly. This was followed by others, which soon became confluent and formed an elongated tumor. These neoplasms were at first hard, then became softened and finally ulcerated. When the patient presented himself for treatment, the tip of the tongue was indurated and showed three points of ulceration. There was no glandular engorgement. Under mercury and iodide of sodium the ulcers healed and the induration diminished very markedly.—*Journal de Médecine de Paris*, August 30, 1884.

The Reduction of Paraphimosis.—The following is the method successfully pursued by Dr. Zakharevich in the reduction of a number of cases of paraphimosis (*L'Abeille Médicale*, No. 32, 1884). After carefully anointing the strangulated parts with oil or vaseline, he places the tips of the thumb and fingers on the glans so as to completely surround it, and then makes firm and gradual pressure. After three or four minutes of this steady pressure, as a rule, the glans is reduced to its normal size. Then, the pressure being maintained by the thumb, the ring, and little fingers, the constricting ring is grasped by the index and middle fingers and the prepuce in this manner drawn down. Reduction is thus accomplished easily and quickly, the most difficult case having required but fifteen minutes for its cure. In the cases treated by him the ages of the patients varied from three to fifty-seven years, and the duration of the condition from twelve hours to thirty days.

Naphthol in the Treatment of Scabies.—Dr. Samuel Rona has treated a number of cases of itch by a ten to twenty per cent. solution of naphthol in oil. If chronic eczema coexist the solution should not be stronger than two or three per cent. In upward of a hundred cases in which the remedy was tried the author never saw any symptoms of poisoning, the only effect of using too concentrated solutions being the production of eczema. The application should be made in the evening, all the parts affected with scabies being thoroughly rubbed with the preparation. The next morning the patient takes a bath, and all the surface reddened by irritation of the naphthol is dusted with rice powder. Usually one application is sufficient for a cure. Sometimes an intense itching persists for some days, but this was attributed to the coexisting eczema.—*La France Médicale*, September 2, 1884.

The Relation between the Ankle Clonus and the Patellar Reflex.—In cases in which the ankle clonus is very marked, as in old hemiplegia or in tabes, it coexists ordinarily with an exaggerated patellar tendon reflex. Certain authors, struck with this coincidence, have referred both phenomena to the same cause and look upon them as of identical semeiological value. This view is opposed by M. de Fleury (*Revue de Médecine*, August, 1884), who asserts that in a large number of

cases the foot phenomenon is met with when the patellar reflex is normal or even abolished. He relates a number of instances in proof of this assertion. He also made some experiments showing that, in cases in which the ankle clonus and exaggerated patellar reflex coexisted, the former could be made to disappear while the foot and knee tendon reflexes persisted. This was done by making the affected member anæmic by means of an Esmarch's bandage. He concludes, therefore, that those who maintain an identity of causation of these two phenomena are in error, and that the ankle clonus is to be explained in some other way.

The Treatment of Snake-Bites.—Mr. J. Mildred Creed, in a paper read before the New South Wales Branch of the British Medical Association (*Australasian Medical Gazette*, No. 10, 1884), states as his belief that many of the alarming symptoms following a snake-bite are due rather to fright, pure and simple, than to the poison received from the fangs of the snake. He relates a number of cases in support of this assertion. The bite had been promptly excised in every case, and only two of the patients presented any alarming symptoms. In one of these cases the patient recovered speedily on being assured that there was no cause for fear, although she had a short time before been apparently at death's door. The other case was simply one of profound intoxication resulting from the large amount of brandy which had been given as an antidote. The author also relates several other cases of people who had died of fright after being bitten by non-venomous reptiles. He does not believe that there is any physiological antidote to snake poison, and thinks that the only effectual means of averting serious consequences is by the prevention of the absorption of the poison. This is best done by the early stoppage of the circulation in the wounded limb by the application of a strong ligature, and the excision of the bite. The reckless administration of alcohol the author condemns as not only useless but harmful. He recommends the administration of ether by inhalation as answering a double indication, that of slight stimulation and of removing the feeling of dread by inducing unconsciousness. The ether should be administered for one or two hours, when the patient may be allowed to recover sensibility to such an extent, as to enable the surgeon to judge of his condition. After this, should it be necessary, he might be again brought under the influence of the anæsthetic and kept there as long as desired. Any other symptoms which may arise are to be treated according to general principles.

The Micrococci of Dysentery.—At a recent meeting of the Medical Society of the Caucasus, Dr. Gaudelin, of Tiflis, exhibited micro-organisms found by him in the intestine and liver of patients dead of dysentery. The micrococci were found in great numbers in the digestive tube, covering the surface and penetrating all the tunics of the intestine. They were especially numerous within and about the veins of the sub-mucous layer and in the muscular coat. In the liver they filled the capillaries and the branches of the portal vein. The author also found bacilli in the mucous and submucous layers of the large intestine, but not elsewhere.—*Journal de Médecine de Paris*, August 30, 1884.

Mild Forms of Typhoid Fever.—Laffoni thus classifies the milder forms of typhoid fever: Forms slight by their duration, forms slight by their intensity, and a third class slight by duration and intensity. Of forms slight as to their duration, constant symptoms are: splenic tumefaction, bronchial catarrh, and fever. The course of this last characterizes the different varieties. The temperature either, as in ordinary attacks of typhoid fever, has three well-marked stages—period of ascending oscillations, stationary period, and period of decline—or is limited to one or two of these stages only. In some rare cases the fever assumes the course of a quotidian intermittent, without repeated rigors or sweats. Of the forms slight by intensity, the duration may be long. These either approach the classical type, or are irregular when the fever is subcontinuous or intermittent, or is partly continued, partly intermittent. Splenic tumor is a constant symptom. These slight forms must be considered due either to a small dose of the poison or to its exhausted activity, or possibly to the mode by which it gained access to the organism, as well as to the conditions of receptivity or organic resistance of the patient. The anatomical alterations are identical with those of ordinary typhoid fever. There is no constant relation between their extension and the intensity or gravity of the clinical form. The diagnosis is very important, especially as regards prophylaxis. It is often very difficult. The splenic tumor, rash, pain in the ileocæcal fossa, evening headache, apathy of the patient, bronchial catarrh, often good appetite, notwithstanding the fever, pulse small, and very often dicrotic, are the chief elements of a sure diagnosis. The prognosis in children is good; in adults it is subordinated to the docility of the patients and to the possibility of complication; in old people, it is always more doubtful. As to treatment, the author recommends calomel for the first three or four days, then mineral acids or benzoic acid. Except the general or partial cold bath, antipyretics, especially in cases of long duration, are harmful or useless.

Abscess of the Cerebellum Consecutive to Otitis Media.—In a communication addressed to the Society of Anatomy and Physiology of Bordeaux (*Journal de Médicine de Bordeaux*, August 24, 1884), Dr. E. Capdeville relates the case of a woman, twenty-four years of age, admitted to hospital suffering from obscure cerebral symptoms. She lay, always on the left side, in a state of semi-stupor, vomiting occasionally, and complaining of an intense general cephalalgia. She had a discharge from the right ear dating back seven months, and recently an abscess had formed and opened spontaneously over the tip of the right mastoid process. At the autopsy the lesions of otitis media with condensing osteitis of the mastoid process were found. The meninges, cerebrum, and sinuses of the brain were all normal, but in the right lobe of the cerebellum was an abscess containing over three ounces of pus. The mode of propagation of the inflammation from the ear to the cerebellum could not be discovered, and possibly the latter may have been merely coincidental and independent of the otitis.

Iodine Injections in Hydrarthrosis of the Knee-Joint.—Dr. Douglas Morton, in *The American Practitioner*, July, 1884, speaks very highly of iodine injections into the knee-joint for the cure of hydrarthrosis. He bases his favorable opinion on the excellent results obtained in four recent cases of this kind. The views of most surgical authorities are against all such procedures, as may be seen from the following extracts: "I have not been so bold as to use injections for the permanent cure of this affection, convinced that the practice must be fraught with danger" (Gross). "Tapping, iodine injections, etc., notwithstanding considerable testimony in their favor, are remedies of doubtful propriety" (Hamilton). "This mode of treatment has been used with great success by several European surgeons; as, however, the plan is necessarily attended by some risk, it should not be employed except in very chronic cases which have resisted other modes of treatment. . . . Even the simple use of the aspirator in these cases is attended with some danger, as shown by fatal results which have occurred in the hands of Dubreuil, and of McDonnell, of Dublin" (Ashhurst). "In very chronic and obstinate cases paracentesis of the joint by means of the aspirator has been employed with marvellous success. Sir J. Fayrer was one of the strongest advocates" (Bryant). "But when these (the usual remedies) have failed . . . the joint must be injected with iodine. Care must be taken to exclude air. . . . The case may be converted into one of acute abscess. But generally

it does well, and the patient recovers with more or less stiffening" (Holmes). "The results of this operation (injecting iodine) may be divided into four classes: (1) Complete cure with preservation of mobility; (2) cure with certain amount of stiffness; (3) complete failure; (4) suppuration and injury to joint. The first and fourth classes are uncommon. The operation should not be done except after trial and failure of other remedies" (Panas, quoted in Holmes' "Surgery"). "Dangerous both to life and limb, and can very rarely be justifiable" (Keetley). "If these means fail, and the absence of false bodies and osteophytes has been verified, the joint may be injected with iodine" (Barwell). "If these means fail, we have a very powerful method of cure at our command in the injection of the joint with tincture of iodine. This plan, a sufficiently bold one, has been much employed by Jobert, Velpeau, and Bonnet. . . . According to the statement of the French surgeons, it has in no case been followed by any serious consequences, but in several instances by a complete cure without ankylosis. . . . In one case of hydrarthrosis of the knee in an old man, in which I employed it, about six ounces of thin synovia were drawn off and a drachm of strong tincture of iodine was injected. Slight inflammation ensued, and the disease, which was of two years' standing, was completely cured. The chief points that appear to require attention are that no inflammation be going on at the time, there being no tenderness or pain in moving the joint, the effusion being quite passive and of a very chronic character, and above all that no air be allowed to enter with the injected fluid" (Erichsen). "Iodine injections in hydrarthrus are made by few surgeons. I have seen them made three times and have made two, always with good results. . . . Cases have also occurred where severe inflammations of the joint have resulted after these iodine injections, which have been most used in France because they are a French invention (of Bonnet and Velpeau); as so often happens in traumatic articular inflammations, the acute serous synovitis often becomes purulent. . . . It is always dangerous to joint and to life, and hence should be done as rarely as possible" (Billroth).

Dr. Morton believes that the prejudice against the operation prevailing in the minds of most surgeons consists of the too lingering remains of a belief long dominant in the professional mind, that the joints, and particularly the knee-joint, could not be surgically interfered with except at great risk. Now that we have learned, especially from McEwen and Ogston, how very tolerant are the joints of the knife and the saw; and since we hold it to be so light a matter to throw iodine into the tunica vaginalis, it does appear anomalous that any one, on any supposed general principles, should consider it highly dangerous to inject iodine into the synovial sac of the knee-joint.

Stress has been put upon the danger of admitting air. The author can understand how importance should have been attached to such an accident before the days of antiseptic surgery. But now he cannot, and in his own operations air was admitted freely—so much so, that when the injected iodine was forced out by pressure a multitude of air-bubbles would come with it. He took pains to bring the iodine in contact with as much of the membrane as had been touched by air, and by this, he believes its admission was rendered perfectly harmless, and therefore made no special effort to prevent it. Without the use of iodine or some other powerful disinfectant, he should regard admission of air into the joint dangerous, and believe it very probable that the fatality occurring in the practice of McDonnell and Dubreuil, mentioned by Ashhurst, was due to this cause. It was said by Volkmann, in his address on antiseptic surgery before the International Congress in London, that results in surgery were no longer involved in the uncertainty of former times. Then the work of the surgeon was like that of the agriculturist, dependent in its issue upon conditions which he could neither anticipate nor control; but now, it is rather like that of the skilled mechanic, the conditions of whose work are largely subject to his control and from whom we may confidently expect results. Dr. Morton does not know that this is true to the full extent of the analogy, but this is certain, that the striking statement places surgery downrightly upon the basis of the inductive method, upon which alone substantial progress is possible. In making a practical application of this method of reasoning to the question before us, he thinks we may safely conclude that two points are definitely and finally settled: first, air may be freely admitted into a synovial sac and no harm result; and, second, undiluted officinal compound tincture of iodine may be safely injected. Any doubt as to these particular points may be regarded as forever eliminated from the question, which is now narrowed down to conditions belonging to the patient's state of health and to his surroundings. Diseased kidneys or bad hygienic conditions rendering the result of any surgical operation doubtful may lead to disaster here. But these conditions may be ascertained by reasonably careful investigation; and, after failing to find any unfavorable condition, we may operate with the expectation of a good result.

The Detection of Mercury in the Urine.—According to Dr. Schuster the ordinary tests are of no value in the detection of very minute quantities of mercury in the urine. He recommends the treatment of the fluid to be examined according to the plan proposed by the chemist Herr Schridde. The urine is acidulated by muriatic acid and submitted to a current of sulphuretted hydrogen and then set aside to stand for twenty-four hours. The sediment which forms contains sulphide of mercury, uric acid, mucus, etc. This is separated by filtration, and both the filter and the sediment which it retains are treated by nitro-muriatic acid, and then dried until no more nitric vapors are given off. The residue is then dissolved in a small amount of water and the solution, slightly acidulated, is treated by the ordinary method of Fürbringer. By this procedure it is possible, Dr. Schuster says, to detect $\frac{1.5}{10.000}$ grain of mercury. *Archives Médicales Belges*, July, 1884.

Typhoid Ulcerations of the Throat.—The following are the conclusions of a memoir read by Dr. E. Rapin before the Medical Society of Geneva: 1, the frequency of the occurrence of typhoid lesions in the fauces is greater than most authors admit; 2, typhoid fever may begin with a sore throat accompanied by indolent ulcerations; 3, the ulcers are superficial, rounded or oval, with slightly elevated borders, and indolent, their seat of predilection is on the anterior surface of the uvula and the anterior pillars of the fauces; 4, the diagnosis is usually difficult, and can only be determined with certainty by observing the general symptoms and the course of the disease; 5, the lesions which characterize them are referable to the lymphatic system; 6, these lesions are identical with those observed in other organs in this disease, and they indicate an identical pathogenesis; 7, they are due to the direct penetration of the micro-organisms of typhoid fever into the follicles of this region.—*Revista de Medicina y Cirurgia Práticas*, August 7, 1884.

Fracture of Inferior Maxilla Treated with Silver-wire Suture.—Dr. J. Craig Miller, of Lake City, writes: "John R——, a miner at the Ulé mine, was thrown from the bucket and fell about fifteen feet. His inferior maxillary bone was fractured at the symphysis. I was sent for (four miles) and arrived about two hours after the accident; found the left half displaced downward about half an inch. It was replaced without difficulty and the teeth firmly fastened together with silver wire, and lead-water and laudanum applied. No other treatment. I thought the wire would be sufficient, as the seat of the fracture was directly in the centre, and it has proved so. The man is over forty years of age."

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, October 11, 1884.

THE AMERICAN PUBLIC HEALTH ASSOCIATION.

THIS body is to meet in its twelfth Annual Session at St. Louis, Mo., on October 14th inst. The session promises to be one of unusual interest, both on account of the locality where the meeting is held, and the importance of the subjects which will be discussed. It is the first time that the Association has held a meeting in what may properly be called "the West." If we may judge by the busy note of preparation for the meeting which reaches us, and the past reputation of the great metropolis of the West for munificent hospitality, the forthcoming session of the Association, at St. Louis, will be on a scale of grandeur hitherto quite unknown to that hard-working body.

All experience proves that however royally any city entertains this Association, it reaps one hundred-fold benefit from the influence which the latter exerts upon the State and the municipal governments. Public opinion is also enlightened, and rendered more favorable to the establishment of a well-organized sanitary administration, and the enforcement of health laws and ordinances.

The Association meets this year at a very important juncture of sanitary affairs, and standing as our great National Congress of Public Hygiene, the results of its deliberations will be of wide import. It is the only organization which, by its national character, its age, its reputation for honest and useful work, and the high official and scientific positions of its members, can at once grasp the great municipal State, national, and international sanitary questions of the day, and formulate principles which must guide the action of legislatures. We look forward, therefore, to this meeting of the Association, with the expectation that, in addition to its interesting daily work, some questions of pressing importance which must occupy public attention during the coming year will be duly considered and suitable action taken thereon.

Perhaps the most important subject which can engage the attention of the Association will be our protection against an invasion of cholera during the next year. It is a fortunate circumstance for us that this Oriental plague, in its progress westward, has dallied so long beneath the sunny skies of Italy. It has thereby given us ample warning of its intended invasion, and enabled the Association to consider, in the most deliberate manner, the defensive measures which should be adopted. This is the first time in the history of cholera epidemic in this country, that there has been an organized body of sanitarians and health authorities prepared, not only to bring to the discussions of the questions of prevention the latest investigations of science and the experiences of sanitarians, but the large majority of them are themselves the official guardians of the public health of their respective communities, and the appointed agents to enforce preventive measures. The country may therefore reasonably expect that, before the Association closes its session, cholera-prevention in all its phases will be discussed by experts, definite lines of action will be determined upon, and such combinations of authorities be organized as will give concert of action in the enforcement of defensive measures throughout the length and breadth of the land.

A second subject demanding the attention of the Association is the condition of our system of quarantine. The simple truth is that our so-called quarantines are a disgrace to the country. They are little else than gigantic political schemes of plundering commerce and travel under the sanction of law. At home and abroad they are the laughing-stock of all advanced students of preventive medicine. Thus far in the history of the Association this great defect in our system of health organization has been allowed to exist without even a protest. Numerous papers have been presented to that body, discussing the general subject of quarantines, but they have led to no practical results. We believe the time is now opportune for the Association to take decisive measures toward reforming our system of coast defences against foreign pestilences, and the country will be disappointed if, in this emergency, the subject is again passed over in si lence.

Again, the relations of the general Government to the measures of preventing the introduction of foreign epidemics into this country, and their spread from one State to another, demands the most serious consideration of the Association.

Through the efforts of the Association a plan was perfected in 1879 of associating the general Government with State and local health authorities in well-devised and concerted methods of action to prevent the invasion and spread of epidemics. For three years that plan worked admirably and effectually, and the country was protected, as never before, from the most dreaded of exotic plagues. The system of co-operation then established, with so much prudence and wisdom, has finally been destroyed by the reckless ambition of men intent only on wielding that power which comes of expending the public funds. The National Board of Health, selected with so much care by the President and Senate, as the agent of the Government in its future sanitary work, has been superseded by an officer of the Treasury Department without law or appointment. The laws, so carefully drawn to guard against the encroachment of National upon State and Municipal authority, and secure the judicious and economical use of the public money, have been purposely allowed to lapse, that there might be no restrictions upon the self-constituted agent who usurped the office and functions of the Board of Health. To-day, therefore, the field of National sanitary legislation is a blank, and it is for the Association

to determine whether the interests of the public health will be best subserved by a well-organized Health Department at the capital, acting under the restrictions of suitable laws, or by an irresponsible bureau officer without sanitary knowledge or experience, and governed by no other law than his own.

Bearing upon the same subject is a question of far wider application, which the Association ought to consider. We refer to *international co-operation in the prevention of contagious and infectious diseases.* There can never be any radical measures adopted and enforced which will strike at the very source of the propagation and spread of epidemic diseases until the great commercial nations of the world combine in good faith, and each in its respective sphere of operations fulfil its whole duty, whatever that may be. And this co-operation can never be established without an International Conference to which these commercial powers shall send delegates. The National Board of Health succeeded in securing one International Conference, by act of Congress, and so popular was the project that twenty-eight nationalities sent delegates. The informal discussions in this body of the measures of international co-operation proved that another conference, the delegates to which were empowered to agree definitely upon propositions to be submitted to their respective Governments, could effect an international sanitary league, offensive and defensive, which would eventually suppress such pestilences as cholera.

The Public Health Association is capable of influencing Congress to take the initial step in calling another conference of commercial nations, and the result could scarcely fail to be an agreement upon the terms of a treaty which would bind these nations to the rigid enforcement of adequate regulations to prevent the transportation of infectious and contagious matters or diseases.

During the present session of the Association the State Boards of Health are to meet in conference. The tendency of this meeting will be to review the project of a separate Association of State Boards of Health. The result of such a step would prove eminently disastrous to public health reform in this country. The Public Health Association stands to-day the foremost of our great national bodies, and is the recognized embodiment of scientific and practical sanitary knowledge and experience in this country. During the twelve years of its existence it has published a series of annual volumes which are unsurpassed by any other Association for real merit. Its influence on public thought and opinion, and on legislation, both State and national, is powerful, and when concentrated on practical reforms, is decisive. Any such dismemberment of the Association as this movement of the State Boards of Health seems to contemplate would be a most inglorious suicide. Far better will it be for the future of sanitary reform and administration in the United States to enlarge the scope and plan of the original organization, so that, while there may be the greatest diversity of discussion, there shall be unity of action, and the voice that shall pronounce the judgment and conclusions of the assembled congress of health authorities shall continue to be that of the American Public Health Association.

THE FIFTH VOLUME OF THE INDEX CATALOGUE.[1]

The appearance of the fifth volume of the Index Catalogue of the Library of the Surgeon-General's office will be hailed with the greatest satisfaction by the writers and workers of the profession, as adding another volume to the admirably exhaustive series which have opened such wonderful treasures of information and reference. Under no other auspices and under no other management could such work be accomplished, than those which centre in the Surgeon-General's office under the direction of the talented librarian, Dr. John S. Billings. In fact in no other country has such a thing been attempted, and it is safe to say, backed by the testimony of those who ought to know, that in no other place has the foundation for such work been laid. The present volume embraces an equal scope with the others, is of equal size, and comprises, as might be anticipated, an almost fabulous amount of references within its limits, viz., from *Flaccus* to *Hearth.* In brief it includes 15,555 author-titles, 5,755 volumes, and 12,596 pamphlets, also 8,069 subject-titles of separate books and pamphlets, and 34,127 titles of articles in periodicals.

The utility of the series proves itself more and more with each volume, and correspondingly indicates the hearty professional endorsement of governmental patronage. The best that can be said is that the good work is likely to go on, and every scholar in the profession will wish it Godspeed.

THE NEW CIVIL SERVICE REGULATIONS AND THE MEDICAL PROFESSION.

An advertisement appears in the daily papers to the effect that "an open competitive examination, under the New York State Civil Service rules, will be held October 22d, at the New York Academy of Medicine, to fill vacancies in the regular medical staff of the Hudson River State Hospital for the Insane, at Poughkeepsie, N. Y." It is further stated, that the examination is open to all graduates of reputable medical colleges.

This announcement, already indicated in a previous issue of The Medical Record, is, we believe, the first application to medical positions of the New York Civil Service regulations, which went into effect last August.

The regulations that have been adopted by this city show the general scope of those for the whole State, and as a knowledge of them may prove of some value to physicians who intend to become connected with the public service we venture to give some of the details here.

The positions which are obtainable now only after competitive examination are those of physician, surgeon, chief of staff of hospital, medical officer, medical superintendent and assistant medical superintendent, inspector of vaccination, or sanitary inspector, and those positions in the Health Department requiring a medical education and experience.

The rules also require an examination of all applicants for the positions of principal matron, head of training-school for nurses, orderly, nurse, and hospital attendant. These positions are included mainly under "Schedule

[1] Index Catalogue of the Library of the Surgeon-General's Office, U. S. Army. Authors and Subjects. Vol. v., Flaccus–Hearth. Washington, 1884.

D," which includes all persons for whose duty special expert knowledge is required; and "Schedule E," which includes physicians, chemists, nurses, orderlies, and other hospital and asylum attendants.

Applicants for medical positions must address a letter to the Secretary of the Municipal Service Boards, New York city, stating their age, residence, nativity, etc.; they must furnish a certificate of good character, and must give evidence that they have been duly authorized to practise medicine and surgery. The examination takes place before one of the three Examining Boards appointed by the mayor, and composed of three citizens. The examination, besides requiring evidence of physical and moral qualifications, includes the following, with the relative weight given to each: medical knowledge, 50; experience, 20; efficiency and accuracy in work, 15; character for maintaining discipline, 15. Naturally, certain variations from this are made in accordance with the character of the position.

It is in the power of the Advisory Board to institute non-competitive examinations for positions in the Department of Charities and Correction.

In regulation 30 it is stated that competitors for "the superior positions in Schedule D" are not obliged to produce a diploma, but a certificate from some reputable institution of having studied two years, or a certificate from a professional man of having studied for three years will suffice.

This provision, as will be seen, furnishes a possible opening for politicians to get in their friends who have not been regularly qualified as physicians.

The Civil Service regulations, if carried out thoroughly, will no doubt assist to raise the character of the medical service. Yet it must be admitted that the character of this service was on the whole very good under the old system. Rumors of late, however, that politics has too much influence in the Health and Police Departments, lead us to look forward with pleasure to anything that promises to remedy these existing or impending evils.

RECOGNITION OF HARD PREPARATORY WORK.

One of the earliest observations which a young physician learns to make is that of the enormous disparity which exists in the education, skill, manners, and general character of physicians. A young man has graduated from a classical or scientific college, has spent three or four years at a leading medical school, has walked the hospitals, has perhaps subsequently taken special courses or studied in Europe. He then settles in practice and finds that he must meet as a brother, and must be estimated by the public in the same rank with a person who, without preliminary training, graduated at some provincial institution, after a course of study lasting practically about two years. He hears derisive comments on this brother's ignorance or on that colleague's offensive ways, he hears the profession ridiculed for its incapacity and various standard weaknesses, and has to take his share of the obloquy, although he can feel without vanity that he is working intelligently and with some success in his chosen art. There seems to him to be something wrong.

There are some evidences that the profession everywhere feels that these differences between doctors and doctors are very great, and that the ill-repute which should fall on the careless and half-educated, should not have to be shared so completely by those who have trained themselves thoroughly, and who are working with an honest ambition.

Some time ago it was proposed in France that a special class of physicians should be established, composed only of those who had shown some evidence of unusual capacity.

In England and this country there is a tendency to indicate, in giving the medical title, the college which bestowed it, provided that institution was one whose character deserved such special designation. Certainly the degree of M.D., in this country, has a very unequal signification, perhaps to a greater extent even than that of A.M.

The establishment and success of the American Academy of Medicine helps also, in a measure, to give credit to those who have taken more than the usual pains to prepare themselves for a learned calling.

We are inclined to favor these plans which aim to give recognition to hard preparatory work. It may be said that such ideas are not "democratic," and that the humble graduate of an obscure school may become a better physician than he who is trained by the most elaborate methods. While this may be true in some cases, certain exceptions do not invalidate the general principle laid down. Hard preliminary work deserves a little recognition other than the slow and uncertain recompense furnished by the public.

THE PATHOLOGY OF SERPENT-POISONING.

A truly scientific account of the lesions produced by snake-poison is so rarely met with that the contribution to this subject by Dr. Romiti, of Sienne, in the *Archives Italiennes de Biologie* (tom. v., fasc. i.), is of great interest.

The victim was a man forty years of age. Within a few moment after receiving the bite, from the *viper aspis*, he fell into a syncopal condition, the heart became extremely slow, and death took place by asphyxia in four hours after the injury. At the autopsy, twenty-three hours post mortem, the body was still in a state of cadaveric rigidity; but it was noticeable that the injured arm was less rigid than the other. The abdomen was enormously distended; and the pupils dilated. The cellular tissue around the wounded surface was infiltrated with a sanguinolent serous fluid, which also invaded the muscular tissue. The neighboring veins were filled with black fluid blood, though the wounds had not entered any vein. The superficial cerebral veins were filled with blood of the same nature, and the pons, cerebellum, and medulla were very much congested. The pulmonary vessels were full of blackish blood, as were those of the abdominal organs; and the intestines were enormously distended with gas. The spinal meninges were congested, and the vessels of the cord engorged.

The most interesting phenomena, however, were those found on histological examination of the blood. Two series of preparations were made of venous blood taken from the vessels of the injured arm. The first, of a single drop of the blood, without any reagent; the second, of blood treated by Bizzozero's method, that of mixing the

blood with a seventy-five per cent. solution of common salt, slightly coloring with methylene violet, and protecting with paraffine. Preparations were also made of blood taken from other parts of the body. The best results were obtained from the examination of unmixed blood, and simply colored with methylene violet. The red blood-globules were normal as to form, but were pale, and the coloring-matter was diffused in the plasma; they had, moreover, no tendency to form rolls, as in the normal condition. Here and there were groups of leucocytes, and in their midst a granular substance. Under a 1,500-power, it was seen that the granular masses were formed of piastrine (Bizzozero), or hæmatoblasts (Hayem). The red disks were rapidly dissociated on the addition of distilled water.

In examining blood which had been preserved the same results were obtained as with fresh blood. The blood which had been kept in vessels remained fluid, of a syrupy aspect, dense, and wine-colored. Three months after death it had the same characteristics, never emitting the peculiar odor of putrefaction, but only a strong empyreumatic odor, very like Liebig's meat extract.

The liver, spleen, and pancreas were examined histologically. The kidneys were in a state of commencing interstitial nephritis. In the liver, the capillaries near the interlobular vein were markedly engorged. The pancreas was extremely soft, and of a pale yellow color; there was complete fatty infiltration of the granular cells, which accounted for the macroscopic appearance of the organ, but this condition may have existed before the injury which caused death.

It is interesting to note here the experiments of Bufalini, in which he injected 30 c.c. of blood from the inferior vena cava of this man into the peritoneal cavity of a guinea-pig; it had no noxious effect whatever. This confirms the results obtained by Albertoni, from which he concluded that the active and poisonous substance of a serpent may be considered as a true poison, and its action may be compared to that of an alkaloid.

BATHS FOR THE POOR IN WINTER.

The communication by Dr. Tauszky in the present issue is one of much interest to all who may have at heart the improvement of the sanitary condition of the poorer classes. The proposition to provide bathing facilities at all times, for the great unwashed, is one which needs only to be mentioned to be commended. It is impossible to estimate the amount of sickness which may be prevented thereby, aside from the individual comfort which is sure to result to such as may be brought to enjoy this very necessary measure. We do not care at present to speak of the details of the plan; these are calculated to take care of themselves when once the soundness of the principles are fully appreciated by the authorities. It is pre-eminently a subject which deserves the attention of the civic authorities, and it is to be hoped that his Honor the Mayor and the Board of Aldermen will give some direct and practical turn to the suggestion. The medical profession can be counted as a unit in favor of it. In fact, we fail to see how any argument can be used against it, except the comparatively trivial one of the expenditure of a small amount of money with a little trouble in the necessary organization. It is, however, one thing to say what the poor should do, but another thing to help them in doing it. The end to be attained by keeping them clean justifies itself beyond argument, and, fortunately, the means are easy of adoption and comparatively inexpensive.

News of the Week.

American Gynecological Society.—By the omission of two words in the transmission of our telegraphic report, it was made to appear that the President's address was not delivered. It should have read, was postponed *until to-day* (Thursday) on account of sickness.

On Thursday morning Dr. Albert H. Smith, of Philadelphia, delivered the President's address, entitled, "The Present Aspect of the Puerperal Diseases," in which he reviewed the literature, the theoretical, and the clinical aspects of the subject, and then devoted considerable space to criticisms on the germ theory of the diseases as set forth by Pasteur.

Malarial Hæmaturia and Pernicious Intermittent Fever.—Dr. Thomas J. Moore, of Richmond, Va., desires us to make some slight changes in the report of his remarks on malarial fever before the Medical Society of Virginia, at its late session (see The Medical Record, September 20, 1884, p. 328). He did *not* say that he had frequently met with cases of malarial hæmaturia in North Carolina, where he had practised, but *in the practice of his brother practitioners in the northern part of Alabama.* He is made, in the report, to say that he uses quinine hypodermically in ordinary malarial fever, whereas he said that he was in the habit of using the salt in that manner in cases of *pernicious intermittent fever.*

The Examination to Fill the Position on the House Staff of the Presbyterian Hospital will be held at the Hospital on November 3d, at 2.30 P.M. For particulars address Rev. Thomas G. Wall, Superintendent.

Remedies for Cholera.—M. Vulpian has made a report to the Academie des Sciences upon two hundred and fifty remedies for cholera, which have been sent by persons desiring to obtain the Bréant prize of 100,000 francs. Some of the discoveries modestly ask that they may be sent to Marseilles in order to test their remedies.

The Washington International Medical Congress.—The Committee on Organization of this Congress has been constituted as follows: Drs. Austin Flint, of New York; I. Minis Hayes, of Philadelphia; Lewis A. Sayre, of New York; Christopher Johnston, of Baltimore; George J. Engelmann, of St. Louis; J. S. Brown, U. S. Navy, and J. S. Billings, U. S. Army.

Significant.—The *British Journal of Homœopathy*, one of the oldest journals of its class, will cease to be published after this year.

An Investigation by the New York State Board of Health.—The New York State Board of Health is said to be about to undertake a collective investigation upon the question as to when a patient convalescent from an infectious disease ceases to be capable of conveying the infection.

The Vermont State Medical Society holds its seventy-first annual meeting at Montpelier on October 15 and 16, 1884. The presiding officer is Dr. S. S. Clark, of St. Albans. Papers are to be read upon "Diphtheria," "Rupture of the Uterus," "Laceration of the Cervix," and other subjects. Dr. J. S. Richmond, of Woodstock, Vt., is Secretary.

Responsibility for Payment of a Consulting Physician.—A test case, says the *Canada Lancet*, was recently tried in Belleville, Ontario, to determine whether or not a patient is liable for the fees of a medical man who is called by a friend or relative. In this case the brother of the patient summoned the consulting physician, who assisted in the amputation of a finger. The patient refused to pay the consulting physician, on the ground that he had not engaged him, and told him to look to the attending physician for his fee. The judge who tried the case ordered a non-suit, holding that the patient was responsible only to the physician he engaged.

Mr. Lawson Tait, while at Hamilton, Ontario, opened the abdomen for supposed gall-stones and found carcinoma instead.

Infectious Disease may Render a Lease Void.—A decision was recently rendered in England by Mr. Justice Field in a case where a claim was made for rent for furnished apartments for the term of the lease, the lessor refusing to occupy the house because, after the lease was made and before the lessee vacated the apartments, a case of an infectious disease appeared in the rooms. The defendant claimed that the existence of a contagious disease in a house rendered it uninhabitable, and the justice rendered a decision favorable to the defendant.

The New York Neurological Society held its first regular meeting for the season, on October 6th. A paper on "Gastric Neurasthenia" was read by Dr. L. Weber, and one on "Pseudo-bulbar Paralysis" by Dr. W. Browning.

The Medical Section of the French Congress for the Advancement of Science.—Among papers of interest read before this section, was one by M. Chaumier on "The Epidemic and Contagious Nature of Acute Pneumonia." The author thought that pneumonia was a constitutional infectious endemic disease, sometimes, though rarely, propagated by direct contagion. It had a germ which could retain vitality more or less long in dwelling-houses. M. Chaumier thought it wrong to poison with drugs persons already poisoned with disease, and advocated the treatment of pneumonia by baths alone.

M. August Ollivier read a paper upon the "Pathogeny of Herpetic Angina," in which he sought to establish the view that it was a neurosis generally of the middle branch of the trigeminus.

M. Bessette urged the use of the thermo-cautery to the entire exclusion of the scalpel in the treatment of spontaneous gangrene.

The Cholera.—It is seventeen weeks since the cholera first appeared in France and over eleven weeks since it appeared in Italy. The deaths from the disease in France have averaged about 375 per week, while in Italy the average has been 1,000 a week. A Roman paper estimates the total number of deaths up to October 1st at 10,800. There is every indication that the force of the epidemic is now spent, in Italy as well as in France and Spain. The total number of deaths from cholera in Italy on October 7th was only 44, in France 8, in Spain 1. A correspondent of the *New York Times* writes that the mastery of the plague in Genoa is really the first fine medical feature of the whole siege. Immediately after the pest broke out with virulence in that city, a fortnight ago, the authorities had the water supply analyzed, and they discovered that of the three sources of supply, that of the Nicolai Company was awful. The municipal works' supply was pretty bad, and that of the Gerzenti Company was pure. Immense and costly efforts were promptly made to shut off the first two sources and to turn the latter water into all the pipes. An immediate improvement was noticed, and the mortality declined after eight days, instead of advancing for weeks, as has usually been the case. We learn by cable also that the commission sent to Marseilles has made an elaborate report of many experiments with microbes, all of which were failures, and that Dr. Klein has shown contempt for the microbe theory by swallowing a quantity of bacilli without harmful result. The Marseilles commission found it could mathematically trace a cholera patient's condition by an hourly examination of the blood, the healthy globules remaining stationary and the unhealthy ones flowing between columns formed by others and taking them gradually off until the column is ruptured. The commission affirms that cholera is not contagious, and it concludes that while we know better than our predecessors what the cholera is not, we do not know what it is.

The Académie de Médecine met September 9th. M. Morel read a paper upon the "Cause of the Normal Evening Rise of Temperature." This was due to three things: food, light, and exercise, of which food was the chief factor. Animals fed during the night had the normal rise of temperature in the morning. M. Dujardin-Beaumetz reported the results of his study of disinfectants. He had reached the conclusion that sulphurous acid is the most efficient and convenient germicide. To obviate the objection that it attacks metals he had recourse to sulphurous acid made from liquid sulphurous acid by the method of Raoul Pictet.

Medicine Takes Curious Freaks in some of the States beyond the Father of Waters. In Nebraska, for example, there is a State University with a Medical Department. Said Medical Department has been taken possession of by certain eclectics, who naturally have started a medical organ, the *Nebraska Medical Journal*. The State evidently supports the Department, for we are told that tuition is free and expenses light. We are pleased to observe also that this free Medical Department has joined the cause of higher education, and will hereafter require attendance upon three courses instead of two. Meanwhile the organ is publishing various discussions as to whether electricity is the cause of the heart's movements.

Mistakes in Words.—A Philadelphia contemporary publishes a newspaper clipping concerning the word "microbe." This word, it states, was coined by M. Charles Sédillot, of Strasbourg, in 1878. The truth is, however, that Professor Pacini used the word "microbio" in 1854, applying it to a micro-organism of cholera.

Valuable Articles Stolen from Physicians' Offices.—At the Tenth Police Precinct Station-house, Brooklyn, N. Y., there are several valuable articles recently stolen by an office-thief, whose operations were very extensive in New York. These articles consist of microscopes, instruments, umbrellas, clothing, etc., still unclaimed, and which evidently belong to New York physicians. The captain is anxious that they be identified and taken away. The station-house is at the corner of Flatbush and Sixth Avenues, Brooklyn.

Subscriptions Asked for a Statue to Dr. Joseph Guislain.—We publish with pleasure the following notice sent to us by Dr. Lewis D. Mason, of Brooklyn: "An effort is being made to secure subscriptions for the erection of a statue to Dr. Joseph Guislain. The members of the Society of Mental Medicine, of Belgium, are actively interested in promoting this object, and desire that all specialists in this department of medicine have an opportunity to subscribe, and that the statue represent the combined subscriptions of the specialists in mental diseases of the world, rather than of any given district. To this end, subscriptions have been received from England, France, Russia, Germany, Italy, Holland, and Sweden, in sums varying from five, to twenty-five francs. The United States, as yet, is *not* represented. We hope the subscriptions from America toward the erection of this statue will compare favorably with those of other countries. Subscriptions may be sent to Dr. B. C. Ingels, Médicin de l'Hospice-Guislain á Gaud, Belgium. List of acknowledgments will be sent to subscribers."

The Limits of Legitimate Advertising.—We commend to our readers' attention the following from the *Iowa Medical Monthly*. The limitations which are here suggested contrast strongly with the sordid and commercial view which allows the unlimited distribution of professional cards with the specialty obliquely indicated thereon. Says the *Monthly:* "Is there such a thing as legitimate advertising, that the physician may use without violating the spirit of the Code? We would answer unqualifiedly, yes, and that its dimensions begin with a good education, gentlemanly conduct, social qualities, industry, and end with the moral effect in the community of his good deeds, distributed by word of mouth, from his friends. This mode of advertising, together with that invaluable quality, tact or good judgment, will always bring success."

Objects and Membership of the American Academy of Medicine.—We have been requested by Dr. Richard J. Dunglison, Secretary, to announce the objects aimed at by the American Academy of Medicine, and also the qualifications necessary for membership. The Academy is growing yearly in members and influence, but it is desired that it embrace in its membership all the physicians in the country qualified therefor. The Constitution says that the objects of the Academy shall be: 1. To bring those who are Alumni of Classical, Scientific, and Medical Schools into closer relations with each other. 2. To encourage young men to pursue regular courses of study in classical and scientific institutions before entering upon the study of medicine. 3. To extend the bounds of medical science, to elevate the profession, to relieve human suffering, and to prevent disease. The Membership of the Academy shall consist of Fellows and Honorary Members. The Fellows shall be Alumni of respectable institutions of learning, having received therefrom: 1. The degree of Bachelor of Arts, or Master of Arts, after a systematic course of study, preparatory and collegiate. 2. The degree of Doctor of Medicine, after a regular course of study, not less than three years, under the direction and instruction of preceptors and professors. 3. When a candidate is an alumnus of a foreign institution not granting the degree of Bachelor of Arts or Master of Arts, a certificate or certificates, which shall be considered as equivalent by the Council and Academy, may be accepted in lieu thereof, provided he shall have subsequently received the degree of Doctor of Medicine. 4. The Fellows shall also have had an experience of three years in the Practice of Medicine, in one or more of its recognized departments, and shall have a good moral and professional character.

The French Association for the Advancement of Science.—This association, which now numbers four thousand members, held its annual meeting at Blois, beginning September 4th. It has a Medical Section which is, we believe, the nearest approach to a National Medical Society that France possesses. The meetings of this Section have not heretofore been productive of any very valuable work, and have not attracted many of the leading members of the profession. The last meeting at Blois, however, seems to have been rather more notable. It was presided over by M. Nicaise, and among those present were MM. Ollivier, Bouchard, and Verneuil.

The New York City Board of Health.—The *Sanitary Engineer* censures our city Board of Health on account of its inefficient action in cleaning out the "slums." The practice of dealing with these places by turning the wretched inhabitants temporarily into the streets and then "squirting copperas-water over the filth," is denounced as a weak and useless measure. The *Sanitary Engineer* believes that all these rookeries should be torn down, if we do not wish the cholera here.

The Nebraska State Medical Society and Preliminary Education.—We learn from *The Journal of the American Medical Association* that the Nebraska State Medical Society has made arrangements for securing a preliminary education to all persons intending to study medicine with physicians of the State. No member of the Society will accept a student of medicine unless he has given evidence of having a certain amount of preliminary education. This is a step that has already been taken by some smaller societies and we trust the example will continue to be imitated, and the practice honestly carried out. Dr. Davis says: "We have seen parties, who in medical society meetings and addresses would advocate the most rigid exaction of a fair standard of general education, take students into their own offices who had not even a respectable common or district school education, and then advise them to attend medical colleges where not only no standard of general education was required, but where a diploma could be obtained for an expenditure of the smallest amount of time and money."

THE INTERNATIONAL OTOLOGICAL CONGRESS.—The Third International Otological Congress was held at Basel, Switzerland, from the 1st to the 5th of September, under the presidency of Dr. A. Burckhardt-Merian, of Basel. We learn from *The British Medical Journal* that the proceedings were opened on Monday at the hall of the University, by addresses from Dr. Sapolini, of Milan, the retiring president, and Dr. Burckhardt-Merian, the president-elect. Addresses of welcome to the town of Basel were delivered by Counsellor Schenck, on the part of the Swiss Federation, and by a delegate from the Canton of Basel. A breakfast, given by the Swiss surgeons to the members of the Congress, followed. On Wednesday the members of the Congress were entertained at a banquet. During the three following days about forty papers were read, and demonstrations were given on subjects bearing on otological science, all of a most interesting, instructive, and original nature. The principal contributors were Politzer, of Vienna; Moos, of Heidelberg; Guye, of Amsterdam; Sapolini, of Milan; Gelle, of Paris; His, of Leipzig; Hartmann, of Vienna; Löwenberg, of Paris; Kuhn, of Strasburg; Albrecht and Delstanche, of Brussels; and Pritchard, of London. It has been arranged that the next Otological Congress be held in Brussels in 1888; and an organizing committee has been nominated, Dr. Urban Pritchard representing England.

DR. THADDEUS JOHNSON has resigned the Chair of Surgery in the Southern Medical College, on account of his health. He is succeeded by Dr. J. McF. Gaston, formerly of Columbia, S. C.

Reviews and Notices.

A TEXT-BOOK OF PRACTICAL MEDICINE: Designed for the Use of Students and Practitioners of Medicine. By ALFRED L. LOOMIS, M.D., LL.D., Professor of Pathology and Practical Medicine in the Medical Department of the University of the City of New York, Visiting Physician to Bellevue Hospital, etc. With two hundred and eleven illustrations. 8vo, pp. 1,102. New York: William Wood & Co. 1884.

THE popularity of Professor Loomis as a medical teacher will of itself do a great deal toward making this book a success. But it need not rely on this. Independent of the author's reputation the volume can speak for itself, as a comprehensive and practical treatise on general medicine. The first thing which impresses the reader is the systematic arrangement of the various diseases discussed. In so far, the author stamps his work with the results of his experience as a clinician. His aim apparently is to draw the outline of general principles with a rigidity and distinctness which admits of no question. This is, however, rather a virtue than a fault, considering the aim of the book. It brings out the strong individuality of the author. It is a positive book from beginning to end, bringing out the strong views of a practical man. The style is terse and perspicuous, the descriptions of diseases and the indications for treatment are direct, practical, and force upon the reader the conviction that the author not only understands his subject in all its bearings, but has the faculty of taking others with him.

While it may be difficult to conceive the possibility of originality in a work like this, there is enough of such an element about it, in arrangement and general treatment, to make it different from any of its kind, and proportionately valuable. Dr. Loomis is particularly happy in making clear the indications for treatment of the different diseases as based upon pathological conditions. He is seen at his best in his discussion of fevers and chest and kidney diseases. It is safe to say that the chapters on these subjects have no equal for practical worth in any language. His divisions are natural, scientifically systematic, and thoroughly practical, really leaving nothing to be desired on the part of the learner who wishes for a broad and solid foundation, upon which he can base his facts of past and future experiences. The difficult subject of auscultation is made strikingly simple not only by word description, but by means of diagrammatic representations. The latter are of the greatest value to the student in making out the relation of the auscultatory signs to the different pathological changes in the lungs and heart. It is difficult to conceive how they could be indicated more satisfactorily.

The chapters on fevers are, as already intimated, of great value. Typhoid fever receives the attention which its great frequency of occurrence demands. There is scarcely any acute disease the treatment of which gives the practitioner more anxiety than this. There are so many circumstances to be taken into account, and so many conditions to be fulfilled, that he cannot study them too thoroughly, or cannot be too well prepared for emergencies. Professor Loomis treats this disease as he does all others, from a clinical standpoint, and the rules which he lays down are eminently safe, and will commend themselves accordingly to the good sense and experience of every one who has seen much practice in that line. These remarks will be found to apply specially to reduction of temperature by cold baths and by quinine. The latter in large doses is a favorite with the author, and his reasons for the practice are very intelligibly given.

The division of fevers is the same as that adopted by most authors, with the exception that the typho-malarial type is treated under the head of continued malarial fever. The author believes that the latter is caused by the combined influence of a malarial and a septic element. His treatment, however, does not differ essentially from that advocated by observers who first studied the disease during the late war. We are inclined to believe that the new name is a good one, and will be generally adopted as best expressing the general features of the disease.

Bright's diseases are treated of under three leading heads: First, the form in which the morbid changes commence in the uriniferous tubules, designated parenchymatous nephritis; second, the form in which the change commences in the intertubular tissue, the cirrhotic kidney; and third, the variety in which the blood-vessels are first diseased, viz., the amyloid kidney. This division is simple and founded on advanced pathology. While speaking of this disease we wish to refer to the admirable rules laid down for treatment, and congratulate the author on the masterly manner in which he has simplified the whole subject.

The figures showing microscopical changes of organs are admirably drawn, and were specially prepared for the work by Dr. M. N. Miller, of the University Laboratory. Of these there is a large number, giving all the leading pathological changes in the tissues of the different internal organs.

In summing up our conclusions in regard to the book as a whole, we repeat that it is the best of its kind and is destined to be the most popular work on practical medicine yet published. It is a matter for great congratulation that by means of his admirable book the distinguished author can now reach thousands who, unfortunately for them, have not had the opportunity of enjoying his teaching in the class-room or hospital ward, and learning those methods of diagnosis and treatment which have tended to make him a successful practitioner in every sense of the term.

Reports of Societies.

PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, October 3, 1884.

DR. A. BRAYTON BALL, PRESIDENT, IN THE CHAIR.

DR. JAMES B. HUNTER read a paper (see page 397) entitled

SOME POINTS IN THE THERAPEUTIC APPLICATION OF HEAT AND COLD.

DR. GEORGE F. SHRADY was ready to endorse Dr. Hunter in his remarks on the relative value of hot and cold applications in the treatment of surgical cases. There was no question in his mind as to the value of the cold coil, as recommended by the author of the paper, in the treatment of traumatic peritonitis. In such cases cold was used as a preventive or arrester of a formidable and rapidly spreading inflammation. In general, however, in the treatment of surgical injuries, when an attempt was made to fulfil these indications, there was often a failure, for the reason that the cases were not seen sufficiently early. This was certainly so in hospital practice. And from other contra-indications these applications were frequently painful to the patients, especially those who were suffering from synovitis and sprains. Consequently he was getting into the habit of using hot applications in preference, particularly for joint sprains, accompanying such treatment with rest and following it with a firmly supporting bandage. In many cases of recent sprain he used nothing but the bandage and rest. When inflammation was fairly under way and incapable of arrest, hot applications were indicated; even in traumatic peritonitis, especially if these were combined with the internal administration of opium in full doses.

In regard to the application of cloths soaked in hot water to oozing wounds there could be no doubt of its value, nor of that of the injection of hot water into stumps in a like condition. Rubber bags filled with hot water formed a very useful means of making hot applications to limited inflammatory troubles.

DR. SAMUEL SEXTON said that the paper called to his mind an early experience in the use of hot water, which had started him to using it a great deal. In 1870 he met a gentleman in the wash-room of the Union League who was unsuccessfully trying to stop a severe nose-bleed by the use of cold water. Dr. Sexton recommended him to snuff hot water up the nose. This was done and the attack stopped almost instantly. Since then the speaker had used hot water as a hæmostatic in all cases, after removing polypi; also as a gargle after tonsillotomy.

With regard to the use of cold, in the early years of his practice he had used freezing applications in the amputation of fingers, as a local anæsthetic. They had prevented suffering and acted very well.

DR. A. A. SMITH had used both rubber and

LEAD COILS IN PYREXIA.

In some cases of typhoid fever, with a temperature of 105° to 105½ F., a single application of the lead coil had reduced the temperature to below 100° F. The coil used had been considerably smaller than those shown by Dr. Hunter. It would not only reduce the temperature but keep it down. In one case of typhoid fever the coil had been kept on continuously for nine days, the temperature being kept below 100°.

Dr. Smith had noticed that the pulse was not always reduced in rapidity correspondingly with the temperature, and he thought that, as a rule, when the temperature is reduced rapidly the pulse is reduced in a much less degree.

He had been for a long time a very strong believer in the reduction of temperature by cold as a therapeutic measure in the pyrexiæ; but he also believed that it was capable of doing much harm. He did not believe in the heroic application of cold in typhoid fever after the tenth or fourteenth day, or when there was a tendency to heart failure, for it might then cause nervous shock. He believed that the applications of cold acted in much the same way as the various antipyretics, referring especially to

KAIRIN AND ANTIPYRIN.

These will reduce temperature, but they also reduce the force of the pulse. The new agent, antipyrin, reduces temperature very powerfully, but it weakens the heart also. The speaker doubted if Americans had the constitutions which would stand the powerful antipyretic measures to which the more stolid Germans are subjected. He felt, therefore, that the safest means of applying cold was the

KIBBEE'S COT.

He had been much pleased, however, with the action of the coils, and they seemed to furnish a safe way of applying cold. The speaker recalled the introduction of cold applications in fever at Bellevue Hospital, in 1870–71. The impression received then was that the application of cold locally in the form of ice-bags, in pneumonia, seemed to increase the tendency to involve new lung tissue.

DR. KINNICUTT had found that the most satisfactory way of applying cold in typhoid fever was by means of the Kibbee cot. He had given it a very thorough trial in St. Luke's Hospital. He had succeeded in obtaining all the good results of the full-length bath without the discomfort to the patient of the latter and the increased labor entailed upon the attendants. A large receptacle for the water was placed upon a stand above the patient's head; a rubber tube was attached, ending in a numerously perforated nozzle. The patient, uncovered or covered simply with a sheet, was then continuously sprinkled from head to foot, for a time corresponding to that usually employed in giving the full-length bath.

Dr. Kinnicutt's experience differed from Dr. Smith's in that, as a rule, he had found, by either the full-length bath or by the application of cold by means of Kibbee's cot, with a reduction of temperature there had been a corresponding reduction in the frequency of the heart's action. Was it not possible that the coil acted in a somewhat different way in lowering temperature from cold water bathing?

DR. A. BRAYTON BALL said, that when he went upon his service at Bellevue Hospital, he had been told that the cold coils had been tried in typhoid fever, and that they had failed. He, therefore, had not tried to use them.

DR. FORDYCE BARKER said that he had been studying clinically the subject of the antipyretic use of cold ever since Dr. Wilson Fox's paper appeared on the "Use of Heat and Cold in Hyperpyrexia." By hyperpyrexia he meant a condition in which the temperature rose to 107° or 112° F. This was an essential fever and a rare one. He had seen but very few cases.

He had thought that in the use of cold as an antipyretic one point had been overlooked in practice, and that was the looking at the pyrexia as the essential disease, instead of regarding it as one of the, perhaps, incidental symptoms, which might or might not demand treatment.

Two or three years ago there began to be a great deal of interest in regard to the use of cold in arresting or preventing and even curing peritonitis. That treatment was most enthusiastically advocated by several surgeons, notably by Dr. Thomas. The speaker, however, was obliged to say that he had reached conclusions in some respects quite different from what he had expected.

He was not certain but that there was a very essential difference between surgical peritonitis and idiopathic, or what he would call, for want of a better term,

OBSTETRICAL PERITONITIS.

He saw quite a number of these cases treated by cold applications. He had studied them with a perfectly im-

partial mind, and he had been disappointed in the results. In many cases he found no such results as Dr. Thomas and others had claimed. There were two cases in particular, which he had in mind, where the coil had been used most thoroughly. At first its influence had been to reduce the temperature and pulse, but after a time the temperature ran up to 104° or 105° F., and the pulse became quick, while associated with it was a very bad general condition. He had found symptoms of general depression and impending pneumonia or bronchitis. The whole abdomen was pale, the capillary circulation almost arrested, with doubtless, in consequence, a hyperæmia of the deeper-seated organs. After removing the coil and the administration of stimulants, and application of turpentine to the abdomen, the most marked improvement occurred. The temperature fell, and the pulse became slower and stronger.

These experiences surprised him, because he had previously seen a remarkable result from cold, and one which led him to expect a great deal from its use.

Two years ago, on one of the worst nights of the winter, he was summoned to see a lady who had been taken suddenly very ill. She had been to the opera that evening, and after it was over had been obliged to stand in the doorway, exposed to the air, while waiting for her carriage. She was menstruating at the time. The menses stopped, and when she got home she was seized with a most violent and prolonged chill. This was followed by intense pain throughout the abdomen. Ginger tea was given, and hot applications made, but the pain went on increasing until, when the speaker arrived, she was nearly frantic. The patient was of a self-possessed and calm temperament, but suffering such agony that she could hardly bear a sheet upon her. The abdomen was puffed up and very sensitive. Dr. Barker gave a hypodermic of fifteen minims of Magendie's solution. After waiting half an hour, there being no abatement in the pain, he sent for an ether-spray apparatus, and at the same time gave her another hypodermic injection of fifteen minims. He thought that there was an incipient peritonitis, and that the cold might act favorably upon that as well as have a direct anæsthetic action. The patient meanwhile had commenced vomiting. He then

SPRAYED THE WHOLE ABDOMINAL SURFACE

until it was very cold, as if it had been covered with ice. The relief was remarkable; the pain disappeared, the hand could be pressed firmly upon the abdomen without causing pain, and the patient went to sleep. The pulse became quite natural also.

Next day the menstruation came on again, and the patient seemed very well. Dr. Barker thought that he had very possibly aborted an attack of peritonitis by the use of the cold.

This case had naturally prepared him to expect much from the treatment of obstetrical peritonitis by cold. But the question was whether, as he had said, the conditions were the same here as in surgical peritonitis. In puerperal peritonitis we have a natural and necessary wasting of tissue. This is not the fact in traumatic peritonitis. The prolonged application of cold has a paralyzing and depressing effect. It reduces temperature, but does it relieve the disease?

The speaker thought that the use of cold in puerperal peritonitis was a measure of doubtful utility, especially its prolonged use. In incipient cases it is extremely useful, but in advanced cases it has a merely temporary effect.

Dr. Barker was led by a recent experience to speak of another point, viz.:

THE SAFETY OF HOT INJECTIONS IN ABORTION.

A lady who had been confined last spring, had made a good recovery, and had spent the summer at a watering-place, came to the city a few days before in order to make some purchases for a new house which her husband, a wealthy man, was building. She had only menstruated once since her confinement, and was at the present time eight weeks advanced in her second pregnancy. She had finished her work and was expecting to start on the next morning for Chicago. In the night (October 2d) she was taken with flooding and pain. Dr. Katzenbach was called in to see her. There was not much hemorrhage, but the pains were severe. An examination showed that there was no protrusion of membranes. Toward morning, therefore, Dr. Katzenbach began to use vaginal injections of not very hot water. He used a Davidson syringe with a nozzle having only lateral openings. While giving the second injection, the patient suddenly went into a state of collapse and appeared as if she were going to die at once. Stimulants were given, and Dr. Barker was summoned. They had been fighting all day to keep her alive. Toward night she had become better and seemed to be reacting from the collapse.

The patient was of a fine, sensitive temperament; and the speaker believed that she had suffered from nervous shock. There was no evidence at all that air had passed into the uterus or Fallopian tubes, and the warm injections had been given very carefully. During the day the membranes and fœtus came away and there was no more hemorrhage, nor had she lost enough blood to account for her collapse.

Dr. Barker had never had an experience like this before. In response to a question he said that he did not think that this case showed that it was dangerous to use hot vaginal injections in abortion. He admitted that the relation between the injections and the shock might have been one of coincidence.

Dr. William M. Polk said that there were three points in the therapeutic use of heat and cold of especial interest, viz., the use of cold in high temperatures, the use of heat in post-partum hemorrhage, and the use of heat as a vaginal application in cases of pelvic inflammation.

With regard to the use of

COLD IN HYPERPYREXIA,

it was capable of doing a great deal of harm. In other words, the mere fact of a high temperature does not itself indicate the use of cold. Several years ago, while visiting the general medical service at Bellevue Hospital, he had used cold applications a great deal. Upon the class of cases which we come in contact with in the hospital it did not act very well. It reduced the temperature, but at the expense of the vitality of the patient. He had found, too, that it was a matter of great importance to look into the condition of the kidneys, because in cases where there is much degeneration, cold is liable to act badly. Such a contingency is to be looked for in typhoid fever and post-partum peritonitis more than after ovariotomy.

As to

POST-PARTUM HEMORRHAGE,

he was much more disposed to rely upon the use of heat than of cold in its treatment. It had seemed to him that when he had used cold there had been such an amount of after-depression as to add very much to the danger of the patient. He had found hot-water injections quite as efficacious in checking post-partum hemorrhage as cold.

As to the use of hot injections in pelvic inflammations, he had found them very valuable. The inflammatory exudation differs, however, in its absorbability in different persons. There is a class of cases belonging to what we used to call the strumous diathesis, and with these the exudations about the uterus are very slow in being absorbed, while the long-continued use of hot water seems to retard rather than help.

Dr. Hunter said that he entirely agreed with Dr. Barker in his opinion as to the use of cold after confinement. He did not think that the cold coil was so good in obstetrical as in surgical peritonitis.

With regard to the fall of the temperature and not of the pulse, Dr. Hunter said that while this might accompany attempts to reduce fever rapidly, he had generally advised a slow reduction.

Dr. Polk referred to a case of scarlet fever where the

HIGH TEMPERATURE WAS REDUCED BY HOT APPLICATIONS.

It was that of a boy who had been showing most unfavorable symptoms. His temperature ran up to 106°, and there seemed little hope of effecting any relief. Dr. Metcalfe advised that cloths be wrung out in hot mustard and water and placed about the patient. In half an hour the temperature began to fall and favorable symptoms set in. It was the only measure that seemed to do any good whatever.

Dr. Smith referred to a case in his own experience almost identical, where a child suffering from scarlet fever received no benefit from cold applications. Hot cloths wrung out in mustard-water produced a fall in the temperature and the development of favorable symptoms.

Dr. C. L. Dana asked if there were yet any trustworthy statistics from American practice showing the efficacy of

COLD APPLICATIONS IN TYPHOID FEVER.

Since the beginning of his practice he had been greatly interested in this subject, having, while an *interne* at Bellevue Hospital, seen it extensively tried, and with doubtful results. Shortly after leaving Bellevue he had collected statistics of the cold-water treatment of typhoid fever in that hospital, and they had not made a favorable showing. The statistics quoted from Dr. Peabody by Dr. Hunter, as to the results of cold applications in typhoid, were of hospital cases and contained many sources of error. The statistics compiled by Brand had in particular been shown to be most fallacious. The speaker said that the result of the long debates on typhoid fever at the Académie de Médecine of Paris had been unfavorable to the use of cold applications. In England, too, the sentiment and evidence against it were very strong. In Germany, recently, an opposition to the once popular use of cold was apparently developing. The speaker only contended that experience had not yet justified the routine use of antipyretics.

Dr. Kinnicutt thought that the statistics of the cold-water treatment of typhoid fever in this country were not sufficiently large to judge from them of its efficacy. In Germany the belief in its efficiency was still fully maintained, he thought. A careful study of the last debate on this subject by London hospital physicians and the statistics furnished by them, led to different conclusions, it seemed to him, from those obtained by Dr. Dana. In France, the opinion of at least the Lyons physicians, was all in favor of the cold-water treatment.

Wound of Abdomen—Protrusion of Intestine—Rapid Recovery without Peritonitis.—The following case, reported to us by Dr. E. B. Ward, of Greensborough, Ala., illustrates the immunity against inflammation which the peritoneum sometimes shows. In a "rough and tumble" fight a man received a wound in the left inguinal region just above Poupart's ligament. After receiving the wound he mounted a horse, rode one mile, put up his horse, and then walked another mile to a friend's house. "When I saw him," writes Dr. Ward, "he was very much exhausted. I found the outer opening about two inches in length, and the inner, penetrating the abdominal walls to the cavity, about one inch. Several folds of intestine with omentum protruded, and they were only returned after anæsthetizing the patient. I first closed the inner opening with interrupted sutures, including the *peritoneum* in the sutures. I then closed the outer integumental wound in the same way, dressing the wound with carbolized dressing, and awaited the result. The patient progressed splendidly without a rise of temperature above 100°, and in less than a week from the date of injury he was up and about his work."

THE NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 2, 1884.

Fordyce Barker, M.D., LL.D., President, in the Chair.

Dr. F. H. Bosworth read a paper (see page 365) on

THE THREE TONSILS—SOME PRACTICAL SUGGESTIONS IN REGARD TO THEIR STRUCTURE, FUNCTION, AND DISEASES.

The President called upon several gentlemen, not specialists in diseases of the throat, to discuss the paper, because of their experience with certain points contained in it. He first said, with regard to his use of the bicarbonate of soda in quinsy, mentioned by the author, that he had been in the habit of seeing a few cases of this disease each year, and until some years ago they almost invariably ended in suppuration; but since he had begun the local application of bicarbonate of soda in not a few of the cases the disease was aborted. A marked instance of the kind occurred in a patient seen with Dr. Bosworth, a gentleman of eminence in literature, who was suffering greatly from threatening abscess. The next morning after the use of the remedy he was found at the breakfast-table.

Dr. Douglas would agree with the author on most points, but there were a few to which he must take exception. He would agree with him, for example, that quinsy was a manifestation of rheumatism, or, especially, of gout, and the treatment which he had employed for this affection was largely that used by the President, namely, bicarbonate of soda. At the same time he gave the ordinary remedies against gout. He had found the gargle and spray of bicarbonate of soda also useful in cases of enlarged tonsil, but one of the most beneficial remedies for this class of cases was a powder composed of one part of menthol to a hundred parts of sugar of milk. He would not always resort to the knife for the removal of the enlarged tonsil; it could be slowly, but surely reduced in size by the persistent use of a powder composed of salt, camphor, ammonia, and sugar of milk.

Dr. F. H. Hamilton was inclined to agree with Dr. Bosworth that the enlarged tonsil should be removed by the knife; yet he had often observed that the enlarged tonsil of childhood disappeared before the twentieth year. He supposed the author, when he said there was no danger connected with the operation, meant not in the acute or engorged stage, and not in those of the hemorrhagic diathesis. The question had been raised whether all or only a part of the tonsil should be removed: he should say all that the knife would include.

Dr. Jacobi believed that the only efficient treatment for the enlarged tonsil was removal; applications would not reduce its size, and where they had apparently done so the reduction was due to some other cause. The enlarged tonsil might remain stationary and appear smaller after the lapse of years, because of the growth of the fauces. As to the danger of hemorrhage, there usually was but little loss of blood, but it might be profuse from cutting into the soft palate—an accident which could not always be avoided. The most efficient means for stopping hemorrhage when it occurred was digital compression, applied, perhaps, for an hour or more. He could not agree with the author's view that follicular tonsillitis was an essential fever; he looked upon it as a local disease. What Dr. Bosworth took to be an essential fever was probably diphtheria, for cases of diphtheria were often overlooked or mistaken for some other affection. It was a great mistake to suppose that every patient sick with diphtheria must necessarily die; there were many mild cases which went unrecognized, and which were all the more dangerous for that reason, as they were the more likely to spread the disease. Dr. Jacobi laid particular stress upon this point because of its importance to the public health.

Dr. Weber had not yet seen a case which went to

substantiate the view that a phlegmonous inflammation around the tonsils was due to the gouty habit. He had found it most frequently in patients of poor general health.

The President remarked that guaiacum had once been strongly recommended in the treatment of quinsy, on account of the supposed gouty origin of the affection; but he had not obtained the results with it which he had been led to anticipate from reading certain articles in the medical journals.

Dr. Post thought the best treatment for the enlarged tonsil was extirpation.

Dr. Hamilton had found the external application of ice or snow the best means for checking hemorrhage after removal of the tonsil.

Dr. Fruitnight had aborted some cases of quinsy by the administration of the tincture of aconite.

Dr. Jarvis again called attention to a distinction which he had made between the soft and hard, or indurated enlarged tonsil, the latter being found in the syphilitic. If the scirrhous tonsil were cut it would surely give rise to hemorrhage, and might result fatally. He employed the knife in the removal of the soft enlarged tonsil, and the cautery or snare in the removal of the indurated tonsil. He did not think any more of the tonsil should be removed than was necessary, for it doubtless served some physiological purpose, as the lubricating of the fauces and protecting the carotid artery.

Dr. Brandeis said he believed in the Darwinian theory of the survival of the fittest: the tonsils had survived some thousand years, had fulfilled some physiological purpose, and he doubted not that they performed their function well, whatever it might be. But the tonsils, like other structures, were liable to disease, and diseased tonsils might be worse than no tonsils at all, and therefore he believed they should in proper cases be extirpated. He then pointed out the advantages of the tonsillitome over the knife in certain cases. Contrary to the experience of Dr. Bosworth, he had found hemorrhage in young subjects rather than in the adult, although not extreme. To prevent hemorrhage, he allowed the patient to sip a solution of tannic acid, and if necessary, he applied pressure. Dr. Bosworth's description of quinsy corresponded with that in Ziemssen's "Encyclopædia," there called peritonsillitis, but Dr. Brandeis could not accept the view that it was always an inflammation of the peritonsular sheath. He recommended aconite and the ammoniated tincture of guaiacum in its treatment until an abscess should have formed.

Dr. Corning had arrested a severe hemorrhage after tonsillotomy in one case by the use of his carotid compressor.

Dr. Bosworth, in closing the discussion, said, with regard to the possibility of reducing the size of the tonsils by astringents, that he believed it could not be done. Their size, however, might be reduced in the young, in whom they were in a state of chronic inflammation, by the new tissue undergoing contracture. This would account for the diminished size of the tonsils on reaching adult life. As to hemorrhage in the young, it was only an oozing; considerable hemorrhage only occurred in the adult. That tonsillotomy was not dangerous was apparent from the fact that in all medical literature not a single fatal case was recorded. The cases in which the carotid artery had been wounded were excepted; this accident could never occur in the hands of a surgeon. In arresting hemorrhage with the actual cautery, the iron should be applied from above downward, that it might not be cooled by the flow of blood before coming in contact with the bleeding vessel. He regarded peritonsillitis a very good name for quinsy, but he did not believe there was a peritonsular capsule proper. As to the tonsils performing their function, he did not think they existed in the normal state, but that they were the result of disease.

The Academy then adjourned.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE CHOLERA—DR. LEWIS ON THE COMMA-BACILLUS AND ITS NON-SPECIFICITY—CANNIBALISM AMONG AN ENGLISH SHIPWRECKED CREW—HOSPITAL SATURDAY—THE HEALTH EXHIBITION AND THE HOSPITALS—DEATH OF MR. NETTEN RADCLIFFE.

London, September 20, 1884.

Despite the prophets of evil, the dreaded cholera has not yet visited us. All possible precautions have been taken to prevent the introduction of a case into the kingdom. Steps have been taken to prevent cargoes of rags from Marseilles and other places from being landed at British ports in cases where there is any possibility of their bringing infection.

With regard to the pathology of cholera, an interesting memorandum has just been issued on the subject by Dr. T. R. Lewis, Assistant Professor of Pathology at the Army Medical School, Netley. Dr. Lewis has lately visited Marseilles for the purpose of studying the subject practically. He criticises Koch's published reports rather closely, but the most startling point in his paper is the statement that comma-shaped bacilli have been found by him frequently in the salivary secretions from the mouths of healthy persons. This is evidently a very important observation, and should it be confirmed by further investigations, will go far to wholly discredit Koch's views on the bacillar origin of cholera. Dr. Lewis is a skilled microscopist and a laborious and patient worker in the field of pathology. Dr. Lewis has also studied cholera practically in India, where he served many years as an army surgeon. His former studies on the *filaria sanguinis hominis* did much to elucidate the pathology of those organisms, and are probably known to many of your readers.

While the story of the Greely Arctic expedition is still fresh in our memories, another horrible tale of cannibalism has just come to light. Three men and a boy going from England to Australia in charge of a yacht, were shipwrecked and drifted about in an open boat for nearly four weeks. As a last resort they killed the boy, and after drinking his blood ate his flesh. His heart and liver were devoured while still warm. It is right to state that the boy was apparently dying. They continued to eat his flesh for several days, when they were picked up by a passing vessel. There is no doubt whatever as to the facts, as the men confess what they have done, and have been arraigned for murder. None of the injurious effects alleged to occur from cannibalism appear to have followed in this case, as, despite their prolonged sufferings, the men seem now to have recovered a large measure of health. Much sympathy is expressed for them in their present position.

Hospital Saturday has realized more than was at first thought, and the total will be more than last year. The workshop contribution is still very small.

The council of the Health Exhibition have handed £4,000 to the Lord Mayor for distribution among the London hospitals.

Mr. Netten Radcliffe has just died after a long illness. He was well known as a sanitary worker, and was for some time assistant medical officer to the local government board.

Menthol Pencils.—These pencils or cones, whose therapeutic value is very limited at best, have become so popular that great adulterations or substitutions are now practised. The ordinary oil of peppermint is probably substituted for the menthol, in large part at least.

THE OPHTHALMOLOGICAL CONGRESS IN HEIDELBERG.

(From our Special Correspondent.)

MURIATE OF COCAINE AS A LOCAL ANÆSTHETIC TO THE CORNEA—NO RADIATING MUSCULAR FIBRES IN THE IRIS—ACTUAL CAUTERY IN SUPERFICIAL CORNEAL ULCERATIONS—OPTICO-CILIARY NEURECTOMY—IS CATARACT THE RESULT OF CHRONIC BRIGHT'S DISEASE?—PROFESSOR ARLT AND HIS RECENT WORK IN GLAUCOMA.

KREUZNACH, GERMANY, September 19, 1884.

SIR: The usual Ophthalmological Congress in Heidelberg has just closed its session, and a few cursory notes at this early date may interest some readers. At this meeting elaborate papers are not read, but condensed statements are presented of the subjects introduced. The notable feature of this Society is that only new things or new phases of old topics are presented. This is not from any expressed rule, but is from the tacit understanding which controls men who are so diligently investigating the unknown in science as are these eager workers. These men have no patience with mere reiterations. Perhaps the most notable thing which was presented was the exhibition to the Congress upon one of the patients of the Heidelberg Eye Clinic, of the extraordinary anæsthetic power which a two per cent. solution of muriate of cocaine has upon the cornea and conjunctiva when it is dropped into the eye. Two drops of the solution were dropped into the eye of the patient at the first experiment, and after an interval of ten minutes it was evident that the sensitiveness of the surface was below the normal, then two drops more were instilled and after waiting ten minutes longer there was entire absence of sensibility, a probe was pressed upon the cornea until its surface was indented, it was rubbed lightly over the surface of the cornea, it was rubbed over the surface of the conjunctiva bulbi, and of the conjunctiva palpebrarum; a speculum was introduced to separate the lids and they were stretched apart to the uttermost; the conjunctiva bulbi was seized by fixation forceps and the globe moved in various directions. In all this handling the patient declared that he felt no unpleasant sensation, except that the speculum stretched the lids so widely asunder as to give a little discomfort at the outer canthus. Before the experiment his eye was shown to possess the normal sensitiveness, and the other eye, which was not experimented on, was in this respect perfectly normal. The solution caused no irritation of any kind, nor did it at all influence the pupil. The anæsthetic influence seemed to be complete on the surface of the eye, and it lasted for about fifteen minutes and the parts then resumed their usual condition. This first experiment was done in the presence of Professor Arlt, of Professor Becker, of the clinical staff, of Dr. Ferrer of San Francisco, of some other physicians, and of the writer. The next day the same experiment was performed on the same patient in the presence of the Congress and with the same results. This application of the muriate of cocaine is a discovery by a very young physician, or he is perhaps not yet a physician, but is pursuing his studies in Vienna, where he also lives. His name is Dr. Koller, and he gave to Dr. Brettauer, of Trieste, a vial of the solution, to be used in the presence of the Congress by Dr. Brettauer. Dr. Koller had but very recently become aware of this notable effect of cocaine, and had made but very few trials with it. These he had been led to make from his knowledge of the entirely similar effect which it has for some year or more been shown to have over the sensibility of the vocal cords, and because of which laryngologists pencil it upon their surface to facilitate examinations.

The future which this discovery opens up in ophthalmic surgery and in ophthalmic medication is obvious. The momentous value of the discovery seems likely to prove to be in eye practice of more significance than has been the discovery of anæsthesia by chloroform and ether in general surgery and medicine, because it will have therapeutic uses as well as surgical uses. It remains, however, to investigate all the characteristics of this substance, and we may yet find that there is a shadow side as well as a brilliant side in the discovery. Professor Kühne, who in the Heidelberg Physiological Laboratory worked out the details of Boll's discovery of the visual purple of the retina, received the news of this new discovery with the liveliest interest. We may, perhaps, get from him a further investigation into its properties. The substance makes a clear solution, and is found in Merck's catalogue.

Another notable statement came from Dr. Eversburch, of Munich, as the result of very exact and elaborate studies, to the effect that there are no radiating muscular fibres in the iris; in other words, that the dilator iridis has no existence in man. It is found, he says, in some animals, and especially in those which have oblong pupils, whether vertical or horizontal, and in the form of fasciculi at the extremities of the slit. He absolutely denies the existence of such fibres in the human eye, and asserts that the fibres hitherto described under this name are nerve-fibres. These revolutionary assertions were received with respect and attention, because the investigator was known to be a careful and competent anatomist. If his declarations should be confirmed, and they will not be lightly accepted, we must find out a new theory for the active dilatation of the pupil. A good deal of physiology will have to be cast into a new form. It is true that the anatomical discussion has not been closed on this point, but in favor of the existence of the dilator stand the names of Merkel, Henle, and Iwanoff among recent investigators. Eversburch has in his possession the preparations of Iwanoff, who died a few years ago, and he knows the nature of the contest into which he enters.

The uses of the actual cautery in superficial forms of corneal ulceration and in some other superficial processes, especially in those of micrococcic origin, were discussed both here and in Copenhagen. There seems to be a general consensus as to the usefulness of this treatment in selected cases of superficial corneal disease, viz., in ulcus rodens, in superficial suppurative processes, in atonic ulcers, and by Nieden in xerophthalmus. Nieden will shortly announce his views in full in an article in the *Archives for Ophthalmology*. He presented a most delicate and elegant form of galvano-cautery which he had devised, and to which he had applied a very delicate and promptly acting key invented by Professor Sattler. Another form of cautery is in use in the Heidelberg Eye Clinic, which has been devised by Professor Becker, and is a very small and utilizable Paquelin cautery. Both these instruments can be handled with nicety and delicacy, and without frightening the patient, and also in most cases without giving him any pain. This treatment, as well as the scraping of such ulcers by a sharp spoon, as does Meyer, of Paris, is founded on the micrococcic theory of the pathology of these processes, and marks another forward step in ophthalmic therapeutics.

Optico-ciliary neurectomy as a preventive of sympathetic ophthalmia has not passed out of practice, as to a considerable degree has become the case among us. So able an observer and logical a reasoner as Professor Schweigger, of Berlin, recommends its performance and holds it in higher esteem than enucleation. He divides the internal rectus muscle to gain easy approach to the nerve, and he lifts it from its bed by a sharp double hook and excises 10 mm. of it. He is said to be extremely skilful in this proceeding, and the very small disturbance which he causes in the structures of the orbit may perhaps explain the success which he has had and the confidence which he expresses in its prophylactic virtue. Among over a hundred cases which furnished the material for his conclusions, in two cases he saw occur in the opposite eye an acute neuro-retinitis, with opalescent infiltration, etc. There was no reduction of vision either central or peripheral. In two weeks the appearance

had entirely passed away without treatment. He regards this inflammation as coming to pass, because neurectomy had been attended by unusual effusion of blood into the sheath of the divided nerve—that this had obstructed the lymph channels, and a process had thus been set up which travelled around by the chiasma to the opposite eye, and there expressed itself in a lymphatic neuro-retinitis such as is well known to occur. The explanation is very plausible. Another most peculiar observation among his cases was, that in one of them the anterior part of the eye was normal, and when the nerve was excised the pupil at once expanded to an extreme degree, more widely than it is possible for atropine to produce. He put eserine into the eye and found that by it the pupil at once became contracted, as is usual with this drug. To this Professor Laqueur justly remarked that absolute proof was thus afforded that, as has been before claimed, the action of eserine is not upon the nerves of the iris, but is directly upon the muscular fibres. A beautiful experiment in physiology was thus made with conclusive result.

A most laborious statistical paper was presented by Professor Becker to elucidate the question whether it is true, as has lately been averred by Deutschmann, that cataract is the result in many cases of chronic Bright's disease. To arrive at a trustworthy conclusion, Professor Becker summed up the results of a most exhaustive and exacting series of studies, first of patients with cataract, whether they had albuminuria; then of persons within the limits of age when both cataract and albuminuria chronica may occur, who were not aware of any trouble of sight or of the kidneys, as to whether they might have incipient cataract with or without kidney trouble, and these persons he found in insane asylums, in poor-houses, in retreats, and among the patients in his clinic and elsewhere; thirdly, he went through the records of 250,000 autopsies which had been made in Vienna of cases of Bright's disease, to see how often cataract had been noted to exist. The final sum of this vast amount of labor was treated according to the principles of the mathematics of the doctrine of probabilities, and the outcome of it all was found in the conclusion that Deutschmann was not justified in his assertions, and that cataract cannot with reasonable and just probability be declared to be an effect of, although it may occur with, degeneration of the kidneys.

It was a delightful feature of this meeting, the presence of the simple-minded and clear-thinking Professor Arlt, who, because he had passed the statutory line of seventy years, had been retired from the chair of ophthalmology in Vienna two years ago. The loving and pious respect in which he was held was delightful to observe. He rose to his feet several times when clinical themes were being discussed, and the range of his memory of facts and cases, and his clear utterances, showed that the edge of his intellect had not been blunted. As a proof of his mental activity, he brought with him a treatise on "Glaucoma," which had just come through the press and in which, in 142 pages, he sets forth with characteristic clearness and acumen, and with great wealth of knowledge both of books and of cases, his views on this disputed theme. Certain I am, from what I have read of it, and from confidential and candid conversation with him, that we shall owe to him much valuable instruction on this subject. His views are sure to make a deep impression and to gain wide acceptance. I hope the book may be elaborately reviewed in some American journal, so as to get the marrow of it in English.

It were hardly modest to speak of the kindly way in which American visitors are treated in these meetings; a man afflicted with less than the average modicum of vanity runs great risk of an acute exacerbation of his frailty, while the average man with average self-esteem simply loses his head.

With much regard, very sincerely,

HENRY D. NOYES, M.D.

A SUGGESTION TO ESTABLISH FREE BATHS AND WASHING-HOUSES FOR USE DURING THE YEAR.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In my reports to the New York Board of Health, during the years 1868, 1869, and 1870, when I made a survey of the Twentieth Sanitary Inspection District, in my capacity of Assistant Sanitary Inspector, I already advocated the establishment of free baths as a sanitary measure for the improvement of the condition of the poor. Since then free baths have been supplied by the authorities in this city during the summer months, but no provision has been made for this luxury during eight months of the year, viz.: from October 1st, to about June 1st. To supply this deficiency, I have recently again laid this matter before the Board of Health and the Mayor of this city, who kindly approved and indorsed my views regarding the establishment of free baths and washing-houses, and promised to co-operate with me to carry out my suggestions, as far as lay in their power.

Regarding the usefulness of such institutions, for obvious reasons, hardly anything needs to be said. But, being a measure of general utility, as a preventive against so-called zymotic diseases—which I would term filth-diseases—I herewith make some suggestions as to how the means could be supplied wherewith to provide these establishments.

1. Part of the excise moneys could be used for this purpose, besides private contributions, if the attention of the public were called to the necessity of such buildings, wherein the poor could bathe and wash their linen free of charge. I am already assured by Mayor Edson, as stated above, that as the head of the Board of Apportionment and of all the city departments he would use his influence for securing from the city the necessary building lots, whereupon these proposed establishments could be erected.

2. The Legislature should pass a law—additional to the Tenement-House Law—whereby every owner of a house should be taxed, say, one dollar annually, additional to the present taxes, for every tenant occupying his house.

3. I would suggest that every emigrant coming to this country should be advised, if deemed necessary by the examining physician at the place of landing, to make use of these cleansing establishments on entering the territory of the United States.

4. Every prison and police station and other public institution should have a bath attached for the use of the inmates.

5. The lower classes, employed by the city, county, or State, should be requested by their superiors to avail themselves of the use of the free baths and washing-houses. Proprietors of large establishments, factories, stores, stables, etc., would follow the example of the authorities by employing by preference, all other conditions being equal, clean and, therefore, healthier people. Consequently a moral pressure could be exercised over servants and employés generally for their own good.

6. While I was stationed on the frontier, and at other military posts, as Post Surgeon in the United States Army, I have often regretted the absence of baths, for the use of the soldiers, connected with their barracks or quarters. The United States Government would no doubt greatly ameliorate the sanitary condition of our soldiers and sailors by erecting free baths for them wherever practicable.

If means were provided by the public authorities or philanthropists for facilitating the constant washing and cleansing of persons and dwellings, I think we would have less of cholera, yellow fever, and other epidemics of filth-diseases, and the germs of many diseases would be, in part at least if not effectually, eradicated.

In closing these remarks and suggestions, written for the consideration and with a view of enlisting the co-

operation of some of the readers of THE RECORD, and *pro bono publico*, I will only add that the plan of establishing cheap, though not free, baths and washing-houses has been tried in London, Eng., within the past four or five years I believe. These are situated in the following parishes: (1) Paddington, (2) Marylebone, (3) St. Pancras, (4) St. Giles, (5) Lambeth, etc. The general arrangement there is: A private bath costs twopence (about four cents) a head, including towels; a higher-class bath, twelve cents; swimming bath, the same price; privilege of use of large room for washing, drying, ironing, etc., at nominal rates. The baths are generally self-supporting and very extensive. Some houses have several swimming baths, each swimmer having a separate box to dress in, etc. RUDOLPH TAUSZKY, M.D.

610 LEXINGTON AVENUE, NEW YORK.

NO MEDICAL HISTORIES OBTAINABLE FROM ST. LUKE'S HOSPITAL, NEW YORK.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Will you be so kind as to publish the enclosed correspondence, which speaks for itself.

I was called to see a gentleman under the circumstances as stated in my letter, and believing that some information in regard to his former sickness would materially aid me in his case, I addressed a communication to Rev. George S. Baker, making inquiries to that end. The enclosed letters are the one I received from him and my answer. I think it should be known, to the medical community at least, that no physician can gain any information in relation to a party who has been a patient in St. Luke's Hospital.

JOS. P. FESSENDEN, M.D.,
Member Medical Staff, Salem Hospital.

SALEM, MASS., October 4, 1884.

P.S.—I thought it best upon the whole to ask you to give place to the correspondence, instead of the public journals.

ST. LUKE'S HOSPITAL, NEW YORK, September 20, 1884.

DR. J. P. FESSENDEN, Salem, Mass.:

DEAR SIR: It is positively against the rules of this hospital to communicate what we learn with regard to the diseases of our patients to any one, save to the patients themselves, if they request it, or to the District Attorney, if he demands it for purposes of justice. We shall not deviate from this rule in the case of Mr. B——. Probably you are not aware that your own is the third letter which has been written me on the same subject.

Yours truly, GEO. S. BAKER,
Pastor and Superintendent.

DEAR SIR: I was exceedingly surprised to learn from your communication, received this morning, that no information relating to the sickness of a patient who had been in your hospital could be imparted to the attending physician of the patient after he left your hands. We have an idea in this vicinity that we have some pretty good hospitals, such as the Massachusetts General and Boston City, both of which are ready to extend such courtesies to the family physician and both of which would receive the condemnation of the public if they refused so to do. The patient, after an absence of six years, without any knowledge of him coming to his sister during that time, suddenly appeared at her home (she is a widow and in straitened circumstances), penniless, poorly clothed, much emaciated, and mentally unsound. I was called to see him and had and now have no doubt but that some information in regard to his sickness in St. Luke's Hospital would aid me in the treatment of the case. You are probably aware that any information conveyed by patient, family, or friends, is held sacred by the attending physician, and you refuse positively to communicate such information for the *benefit of the patient* whose welfare is entrusted to me. It seems to me to be an unheard-of procedure. I do not know that the fact that you have been written to, asking for information three times, concerns me in the least, even did I know it, which I do not.

If I can elicit no facts from you, I shall publish your letter in the New York papers, with an explanation in regard to it. I think the public should be made acquainted with such a rule of the hospital for its guidance.

Very respectfully yours,
J. P. FESSENDEN, M.D.,
Member Medical Staff, Salem Hospital.

SALEM, MASS., September, 1884.

[It is difficult to understand upon what grounds any public hospital can refuse to give to a medical gentleman in charge of a patient such information as was solicited by our correspondent. We should like to have some explanation on this point from the hospital authorities.—ED.]

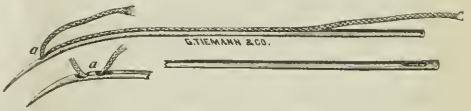
New Instruments.

A NEW NEEDLE FOR CONTINUOUS OR INTERRUPTED SUTURE.

BY G. WACKERHAGEN, M.D.,

BROOKLYN, N. Y.]

THE under surface of this needle is grooved to within three-eighths of an inch from the point, when the channel is crossed by a narrow depressed bridge; under this the thread is passed, and returning over the bridge again falls into the groove of the needle, thereby preventing obstruction to its passage through the tissues. There is



also an eye near the blunt end so that it may be used for continuous suture.

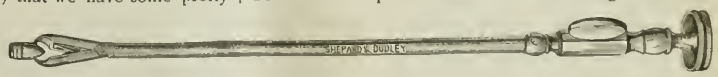
The special advantage claimed for this needle is that it is not necessary to remove the needle-holder while operating by interrupted suture. The needle having passed through the flaps, the thread is caught by dressing-forceps and the needle withdrawn.

A NEW BULLET FORCEPS.

BY WILLIAM R. LEONARD, M.D.,

NEW YORK.

THE accompanying cut represents a new and improved bullet forceps. For the last twenty years nothing has been done to improve the method of extracting bullets. All



instruments in use for this purpose up to the present time are deficient in many respects, and are apt to slip after they have engaged the bullet. The instrument here presented consists of a steel cylinder inclosing a steel stylet riveted to two jaws, which are hinged and terminate in short steel teeth, which take a firm hold upon any part of the bullet by burying themselves in its substance. The instrument is introduced closed. When the bullet is reached the jaws are opened by turning the screw at the proximal end, and the instrument is then pushed up so that the jaws grasp the bullet; a few turns of the screw bury the teeth in the bullet firmly and make it part and parcel of the instrument.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 28 to October 4, 1884.

BENTLEY, EDWIN, Major and Surgeon. Granted two months' leave of absence, with permission to apply for two months' extension—to take effect upon assignment to duty in the Department of Texas of Surgeon F. L. Town. S. O. 121, Headquarters Division of the Missouri, September 30, 1884.

BARTHOLF, JOHN H., Captain and Assistant Surgeon. Assigned to duty at Fort Ringgold, Texas, as Post Surgeon. S. O. 129, par. 5, Headquarters Department of Texas, September 25, 1884.

CRAMPTON, L. W., Captain and Assistant Surgeon. Granted leave of absence for one month and ten days. S. O. 60, Headquarters Division of the Atlantic, October 2, 1884.

GIBSON, R. J., First Lieutenant and Assistant Surgeon. Assigned to duty as Post Surgeon, Fort Winfield Scott, California, relieving Assistant Surgeon A. S. Polhemus. S. O. 115, par. 1, Headquarters Department of California, September 23, 1884.

POLHEMUS, A. S., First Lieutenant and Assistant Surgeon. Upon being relieved, to report to commanding officer Fort McDermit, Nevada, for duty as Post Surgeon. S. O. 115, par. 1, Headquarters Department of California, September 23, 1884.

WHITE, R. H., Captain and Assistant Surgeon. To report to commanding officer Angel Island, California, as Post Surgeon, relieving Assistant Surgeon C. K. Winne. S. O. 115, par. 1, Headquarters Department of California, September 23, 1884.

WINNE, C. K., Captain and Assistant Surgeon. Upon being relieved, to report to commanding officer Benicia Barracks, California, for duty as Post Surgeon, relieving Surgeon C. C. Byrne. S. O. 115, par. 1, Headquarters Department of California, September 23, 1884.

EVERTS, EDWARD, First Lieutenant and Assistant Surgeon. Granted leave of absence for one month, with permission to leave the limits of the Department. S. O. 145, Headquarters Department of Colorado, September 24, 1884.

Official List of Changes in the Medical Corps of the U. S. Navy, during the week ending October 4, 1884.

STEWART, HENRY, Surgeon. Granted leave of absence for one year, with permission to leave the United States. October 15, 1884.

EDGAR, JOHN M., Passed Assistant Surgeon. Detached from the Nantucket and placed on waiting orders. September 29, 1884.

HARMON, G. E. H., Passed Assistant Surgeon. To the Naval Academy. September 30, 1884.

BERTOLETTE, D. N., Passed Assistant Surgeon. From the Naval Academy to the Dolphin. October 4, 1884.

ROGERS, BENJAMIN F., Passed Assistant Surgeon. To the Naval Academy. September 30, 1884.

COOKE, GEORGE H., Surgeon. From the Naval Academy, and placed on waiting orders. October 2, 1884.

WHITING, ROBERT, Passed Assistant Surgeon. From the Naval Academy and placed on waiting orders. October 4, 1884.

BREAKFAST.—In the time of Henry VIII., the Queen's Maids of Honor had each a chet loaf, a manchet, a *gallon of ale*, and a chine of beef for their breakfasts. What did they have for dinner?

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 4, 1884:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.								
September 27, 1884.....	2	46	19	4	13	27	0	0
October 4, 1884.....	1	60	32	2	22	39	0	0
Deaths.								
September 27, 1884.....	0	13	3	5	5	10	0	0
October 4, 1884.....	0	13	0	2	5	19	0	0

LOVAGE.—The *levisticum* of botany has, on Dr. Johnson's authority, a virtue in the relief of rheumatism. He says: "Take equal quantites of flour of sulphur and flour of mustard seed, make them into an electuary with honey or treacle, and take a bolus as big as a nutmeg several times a day, drinking after it a quarter of a pint of the infusion of the root of lovage. The relief is speedy and lasting." But perhaps sulphur will answer alone. Lovage, like sassafras, belongs to a large class of plants containing an essential oil, which have always been employed as carminatives, diuretics, emmenagogues, and digestive stimulants, in flatulent dyspepsia, amenorrhœa, dropsy, and rheumatism.

FOR HYPERHIDROSIS OF THE FEET Dr. Duhring has used the following with good results:

℞. Zinci oleati..... ʒ ij.
Amyli,
Talci .....āā ʒ iij.
M. Sig.—Dusting powder.

This was applied to the feet after they had been washed with a lotion of tincture of belladonna.

THINGS TO TRY.—Dr. Robert A. Reid, of Boston, in his *Eclectic Journal*, suggests the following "things to try" when ordinary measures fail: Try pop-corn for nausea and vomiting of pregnancy; try sun-bath for rheumatism; try cranberry poultice for erysipelas; try lager beer as a gargle for sore throat; try eating fresh radishes and yellow turnips for gravel; try eating onions and horse-radish to relieve dropsical swellings; try taking cod-liver oil in tomato catsup if you want to make it palatable; try snuffing powdered borax up the nose for "cold in the head;" try hard cider—one glassful three times a day—for ague or rheumatism; try breathing the fumes of turpentine or carbolic acid to relieve whooping cough; try a cloth wrung out of cold water put about the neck at night, for sore throat; try planting sunflowers in your garden if you live in a malarial region and the travelling is bad.

A CASE OF ROSE COLD.—Dr. F. B Streeter sends a history of a case of "rose cold," as suggested by Dr. Mackenzie: "Mrs. William B——, aged thirty-five years, native of this State, of Dutch descent, married, and barren. With the exception of an uterine disease, which is the probable cause of her sterility, she is in a fair state of health. I first saw her some three years since. She was suffering from an intense coryza, and attributed it to the fact that while walking in the dark she had accidentally brushed against a bush laden with full-blown roses. She explained that she had been affected thus by roses since her childhood, and as she is a lady of intelligence her case seems to be clearly one of 'rose cold.' She has no catarrh or any other disease of the respiratory system, nor is she similarly affected by the pollen of any other flower or plant."

CONTRIBUTIONS TO

THE ANATOMY OF THE LEMNISCUS.

WITH REMARKS ON CENTRIPETAL CONDUCTING TRACTS IN THE BRAIN.

BY E. C. SPITZKA, M.D.,

PROFESSOR OF NEURO-ANATOMY AND PHYSIOLOGY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

(Continued from page 397.)

II.

III.—THE COMPONENT OF THE LEMNISCUS WHICH PASSES THROUGH THE INTEROLIVARY LAYER.

IN the sequel it is my intention to discuss only a portion of the axial fibre-systems which have been by various authors [1] designated as lemniscus, under that name, leaving the *critique* of this designation to the concluding remarks. In the lower (caudal) part of the oblongata these tracts are found in such relations as to enable us most readily to understand their connections with the important spinal tracts, and the older authorities and some of the more recent ones include the olivary fasciculus, which is larger than the interolivary layer.

A section made at the level indicated in the accompanying figure reveals the following prominent gray

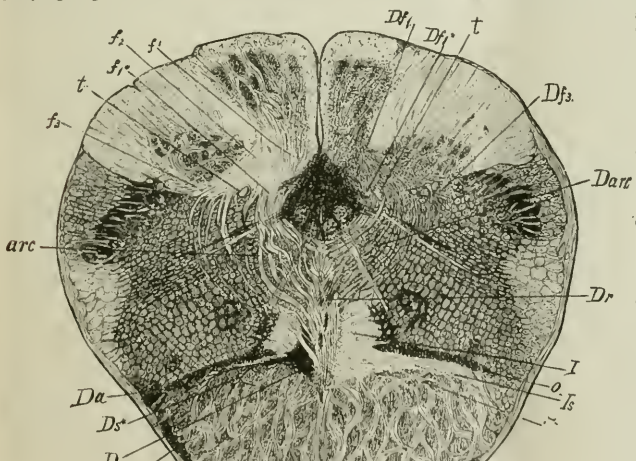

FIG. 3.

(ganglionic) substances: First, the nuclei of the columns of Burdach and Goll; second, the ganglionic substance of the column of Rolando; [2] third, the gelatinous gray substance surrounding the central canal, in whose distal portions the hypoglossal and vagus (vago-accessorius?) nuclei begin to appear; fourth, the reticular gray substance in

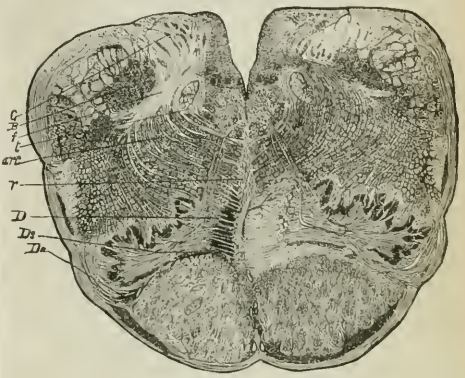

FIG 4.

the field intermediate to the bridge of gray matter (which unites those nuclei which, for brevity's sake, I shall term the nuclei of Goll, Burdach, and Rolando), the central gelatinous substance, and the lemniscus; fifth, the olivary nucleus, which in this level is represented only by that portion which is known as the internal accessory olive (*o*); sixth, the small nuclei interpolated in the external arciform fibres (*na*). Of these various gray substances the nuclei of Burdach and Goll and the olive have relations to the lemniscus, thus indicating what an extensive territory this fibre agglomeration occupies.

Surrounding on its medial and dorsal confines the nucleus of Goll, and capping dorsad the nucleus of Burdach, are the fibre-tracts of the columns of the same name. As we proceed cephalad we find that the mass of these columns undergoes a gradual reduction. In the main this reduction appears to be effected by the entry of the fibres into the nuclei. These are fielded off by intersecting delicate fasciculi into numerous subnuclei. The nearer the spinal cord, the more compact (and small) is the nucleus of Goll (*nucleus funiculus gracilis*); the nearer the middle of the middle olivary altitude, the more scattered and subdivided are its cell-groups, and the more distinctly does it appear as if the whole mass of the column of Goll broke through the nucleus to separate into the strands of the internal arciform fibres (Fig. 4). Much as the anatomical appearances suggest the existence of a direct connection between the column of Goll and the internal arcuate fibres mentioned, a study of the phenomena of secondary degeneration does not sustain the existence of such a connection as a direct one.

In the case of secondary degeneration to which I have

[1] Except the one in which the term is employed by Meynert in his last work, Psychiatrie, Part 1., which is over-ample, and evidently intended to justify certain of his older and untenable views, which he seems disinclined to abandon.

[2] This contains three categories of ganglionic substance, viz., the convoluted lamina corresponding to the gelatinous head of the posterior horn of the spinal gray, the subjacent paler staining spongy gray substance, and the intercalated gray islands in the root itself, containing cells like those of the nuclei of Goll and Burdach. The absence of the gelatinous head in reptiles would seem to indicate a relation to one of the specialized forms of sensation, whether of contact or temperature, more likely the latter.

alluded, I found that the fasciculi interpolated in the nuclei of Goll and Burdach showed a reduction in size on the side *opposite* to the degenerated lemniscus field. The third and fourth figures accompanying this paper illustrate this relation. In Fig. 3, the dark field *Da*, *Ds**, *D*, which represents the descending degeneration, connects by diagonal raphe strands (*Dar*c), which pass into the degenerated fields *Df*1, *Df*1*, and *Df*3, and these in turn connect with the degenerated internuclear fasciculi in the nuclei of Goll and Burdach.

The part of the lemniscus degenerated in the above case corresponds to Flechsig's interolivary stratum.[1] In a section of the level, shown in Fig. 4, this stratum is L-shaped (the dark area *D*, *Ds*, *Da*), consisting of a vertical field (*D*) which fills up the interval between the raphe (*r*), the internal accessory olive, and the pyramid tract, and a nearly horizontal field (*Ds*) which lies between the halo of the denticulate (main) olivary nucleus and the pyramid; it extends with an angular swelling to the point of emergence of the hypoglossal nerve-roots *Da* (see corresponding designations of Fig. 3). Inasmuch as the degeneration can not be traced into the tracts included in Burdach's and Goll's columns, but only into the nuclei of these columns, it is to be inferred that the latter are interpolated between two divisions of one and the same tract. In other words, that the spinal columns of Goll and Burdach terminate, anatomically speaking, in their nuclei, and that from these "interrupting" nuclei a physiologically continuous tract arises which passes through the fields *f*1, *f*2 (Fig. 3) into the arcuate fasciculi (*arc*, Figs. 3 and 4), decussating in the piniform decussation,[2] and after crossing the median line continuing brainward, in the interolivary stratum of the oblongata and pons (*I*, Fig. 3).

As in cases of prolonged typical locomotor ataxia the columns of Goll undergo secondary degeneration, it is to be assumed that the essential primary lesion of that disease affects the nutrition of those columns secondarily either by the involvement of the posterior rootlets or of the gray substance in which they terminate or through which they pass.[3] The connection of the column of Goll with the sensory nerves of the inferior extremity has been positively established. It is evident, then, that the column of Goll conveys brainward certain impressions which occur in the posterior (inferior) half of the body. It is exceedingly probable that those impressions which are most regularly affected in locomotor ataxia, namely, those informing the subject of the position of his lower limbs in space, which enable him to regulate their muscular movements in conformity with the resistance to be overcome, and which are ordinarily classed under the head "muscular sense," are the ones conducted by these columns. In order to become appreciated, however, these columns must be connected with higher centres than the nuclei of Goll and Burdach; the regulation of these movements which are most constantly affected in locomotor ataxia, while not altogether removed from cerebellar control,[4] is a function of the cerebral hemispheres. It is evident, therefore, that after interruption—for some thus far inscrutable purpose—in the nuclei of Burdach and Goll, another tract *must* leave these stations to reach the cerebrum. This tract is the one just described and visible in its decussation in Figs. 3 and 4, that is, the interolivary layer of Flechsig.

Meynert long ago recognized the necessity of establishing a connection between the posterior columns of the spinal cord and the cerebrum. The method he followed in delineating his projection system was to take physiological and pathological facts as so many guides in the labyrinth of cerebral fibre-tracts, and then to fit the demonstrable nerve-strands that happened to correspond, as he supposed, to the required physiological paths into the maps thus constructed. Knowing that the posterior part of the internal capsule conveyed sensory functions, and that the posterior columns of the cord did likewise, he traced the required connection between them through his so-called upper or sensory pyramidal decussation into the lateral part of the pyramids, along these into the lateral part of the *pes pedunculi*, and thence by an easy transition into the posterior division of the internal capsule. A diagram representing this supposed tract is extant in Huguenin, whose work is in the main a popularization of Meynert's system, and in many places evidently inspired by the black-board diagrams which this great master of modern cerebral anatomy illustrated his lectures with.

Grossly erroneous as Meynert's representation just detailed is now known to be, in many features it is correct; and this has been (intentionally or unintentionally) overlooked by those who have condemned his views.

It is a fact that the continuation of certain portions of the sensory tract from the cord to the brain decussates, in the upper fine-bundled decussation called by Meynert the "upper decussation of the pyramids." The view held to-day differs from Meynert's chiefly in regard to topographical nomenclature: 1. As the decussation in question is not connected with the pyramid tract proper, it is no longer called the upper "pyramidal" decussation. Flechsig's followers might perhaps term it the "decussation of the interolivary stratum." In want of any other brief designation, and recognizing that it could no longer be considered a part of the pyramidal decussation, I termed it the piniform decussation.[1] Certainly it resembles in section nothing so much as a fir-cone (Fig. 4, near *r*; Fig. 3, near *Dr*). 2. Meynert was partly correct in tracing the fibres of this decussation to the lateral part of the pyramids, as these bodies were considered at the time he wrote his treatise. The pyramid tract of to-day covers a much more limited area than the one assigned to it by anatomists of the last decade. Even Henle, who wrote after Meynert, represents them as extending dorsad, between the raphe and the roots of the twelfth pair, nearly to the floor of the fourth ventricle, making them include the *strata* interolivaria and the inner division of the reticular field of Meynert.[2] 3. Even as the pyramids are demarcated to-day there is some little justification for Meynert's theorem. *Fibres from the nuclei of Goll and Burdach do pass into a field connected with the true pyramid tract.* I expressed a surmise to this effect in the description of the case of secondary degeneration repeatedly referred to in the course of this paper. It was doubtful to me then whether the fibres thus traced by their degeneration (*Ds**, Fig. 3) represented a communication of the interolivary and the pyramidal tracts, or whether they were the fibres which, leaving the pyramids, pass to the hypoglossal nuclei, and (subjected to the pressure of the shrinking field of the interolivary layer through which they passed?) underwent a slight retrograde degeneration.[3] Opposed as this latter alternative appeared to be by the general rule supposed to govern secondary degenerations, it became definitely disposed of to my mind after a complementary study of secondary degeneration of the pyramidal tracts. Not only is it impossible to trace degenerated fibres to the hypoglossal nuclei in any such situation as that indicated by *Ds**, but *the very fasciculi within the pyramid*

[1] From the supposed connection with Meynert's *stratum intermedium* I applied that name to the interolivary extension. I have resolved for the present to discontinue its employment, as the same designation has been employed in such different ways by Wernicke and Meynert himself.

[2] Upper fine-bundled or sensory decussation of the pyramids of Meynert.

[3] It has been lately shown that the columns of Clarke, which are by Flechsig supposed to have a relation to the posterior rootlets, are similarly involved in advanced cases of this disease.

[4] On comparing a number of types of this disease it will be found that in some the ataxia has no actual cerebellar character, but in others not. In the latter the same complaint found in *cortical ataxia*, that distance is misjudged or the length of the limb or a segment of it seems increased or decreased, is made.

[1] Architecture and Mechanism of the Brain, Chicago Journal of Nervous and Mental Diseases, 1879, 1880.

[2] It is only on this assumption that his designation of the mesal accessory olive as a "nucleus pyramidalis" is comprehensible.

[3] A Contribution to the Morbid Anatomy of Pons Lesions; beiog No. 1, Series III., of Contributions to Neuropathology, based on researches conducted in the author's laboratory. Reprinted from the American Journal of Neurology and Psychiatry for November, 1883.

field which are affected in degeneration of the interolivary stratum were found comparatively normal in a case of intense double descending (degeneration of the pyramid tracts.[1] Whether these fibres, after leaving the interolivary layer, re-enter it, abandoning their intra-pyramidal course, I am at present unable to determine. But the fact here stated shows that there was much more basis for Meynert's view than Flechsig seem to have been aware of.

Flechsig assumes, for the sake of simplifying matters, that the fibres of the posterior columns which represent the cephalic continuation of the posterior roots of the spinal nerves abut in the nuclei of the columns of Goll and Burdach, without committing himself directly to the view that all of them do so. If we believe that the laws of secondary degeneration are invariable, that the course of such degeneration is always in the direction of functional transmission,[2] then, undoubtedly, the columns of Goll and Burdach must terminate in the nuclei named after them, with that portion of their fibres which, in my opinion, represent Flechsig's interolivary layer continued down (after nuclei interruption); for in my case of a secondary degeneration of six years' duration not a degenerated fibre could be traced beyond the nuclei, though these themselves were atrophic.

In speaking of these fibres, Flechsig battles with an imaginary opponent. He says,[3] "The view that the posterior columns pass to the cerebrum chiefly through the mediation of the interolivary layer (and the longitudinal fibres of the reticular formation?) has much more in its favor than the view that the posterior columns are exclusively connected with the cerebellum." He does not inform us who announces such a view. The one generally held up to the time of Flechsig's writings, was that of Meynert, who traced a part of the posterior columns (correctly) to the cerebellum, and another portion to the cerebrum, through his so-called "upper fine-bundled decussation of the pyramids." Flechsig was destined to confirm this view of Meynert's, with some toponomical corrections above referred to, to demonstrate much more satisfactorily than Meynert ever dreamed of doing that this decussation embodied the continuation of posterior column fibres, and to correct some erroneous details in Meynert's scheme. All this does not justify his repeated innuendoes against the latter on the one hand, and the suppression of its meritorious features on the other. Indeed, it would not be difficult to show that if Flechsig does not owe to Meynert the hint which led to his following the embryological method with such signal and acknowledged success, he would be compelled to confess to having had but an imperfect knowledge of the cerebral anatomical literature extant when he undertook his great work.[4]

The "atrophy method," and the "development method" of Flechsig have undoubtedly cleared up much in the cerebral labyrinth which other methods were inadequate to unravel; and if it be true, as I have repeatedly stated to my class, that the progress made in cerebral anatomy during the last ten years, quantitatively speaking, exceeds that made during the previous one hundred and fifty years, it is to these two methods that the credit is chiefly due. But while recognizing the service which Gudden, Flechsig, and their pupils have done and are doing, it is not yet demonstrated that their methods are as exact as their advocates allege. To show the justice of this doubt it would suffice for me to refer to the various controversies which Mayser and Forel, on the part of the Gudden school, and Flechsig have indulged in. The results derived by both methods ought to be identical, if both were absolutely correct. They differ, however, in some respects and several details; and notwithstanding that it has been implied—and particularly by one who has undertaken to interpret and report the results of industrious continental laborers, after a hurried visit to their laboratories—that the day of microscopic sections is past, I believe that neither the results of the atrophy method nor those of the embryonic method should be accepted unless they are gauged by a study of sections and made to harmonize with their revelations.[1]

In order to show that those who have most severely criticised Meynert, and at the same time most sedulously belittled the extent of our indebtedness to him, are not themselves free from errors, often far more serious than those committed by that authority, I will refer for a moment to the latest proclamations made by Flechsig regarding the cerebellum.

Flechsig is undoubtedly justified in attaching great importance to the peculiarities of tract development, observed in a child born without a cerebellum. It is difficult to understand, however, how he can state: "This brain united the advantages of developmental and degenerative differentiation of the central white masses, inasmuch as all fibre-tracts connected with the cerebellum were absent or atrophic, while all others were developed to an extent corresponding to the end of the period of fœtal life, being partly myelinic and in part amyelinic." The cerebellum is too important an ingredient of the central mechanism to be eliminated without producing far-reaching defects in development elsewhere. It is not probable that the remote centres connected with the cerebellum were, as such, normally developed; the mental disturbance noted with defective development of the cerebellum is probably to be explained on the ground that its absence is associated with other defects, indeed, that it is only an intensified expression of a general defect in cerebral development. This is the proper explanation of the intellectual deficiency noted with cerebellar atrophy, and not the wild and startling tentative suggestion of Flechsig,[2] who asks whether the existence of the commisural cortical gray of the cerebellum does not explain (by vicariation) the absence of mental disturbance noted in cases where the corpus callosum is absent! This suggestion exceeds in fancifulness, and in lack of foundation, anything ventured by Meynert, who is harshly criticised by Flechsig, but who rarely abandoned the channels of logical reasoning based on the facts as known, or supposed to be known, in his day, to such a grievous extent, at least not before Flechsig wrote.

It is an interesting and important question, one requiring great care and a comparison of numerous anatomical and experimental facts to determine, what qualities of sensation are transferred to the brain by the piniform, or upper (sensory) decussation of the interolivary stratum. Wernicke[3] first formally considered the inconsistency between the well-known phenomenon of crossed hemianæsthesia in spinal hemisection and the assumption of a redecussation in the oblongata. Many who have never published their doubts probably raised the above questio in their minds. More recently Starr[4] has reviewed th entire question and collected a number of valuable an not generally accessible cases, which justify his arriving at

[1] This I found to be as described in specimens of another's unpublished case of descending degeneration of both pyramid tracts, and in a unilateral case of my own.

[2] Which is not the case. [3] Plan of the Human Brain, p. 22.

[4] For in the following lines is contained the suggestion and essential feature of Flechsig's method, and one of his conclusions imperfectly expressed; indeed, Flechsig knew of them, referring to them in his book; recognizing that Meynert is the first to suggest that the development of myelin in the nerve-tracts was destined to reveal important features of the development and structure of the central nervous system. "The absence of the striæ acustici in all animals does not indicate an absence of its nervous bundles, but only the invisibility of these due to their axis cylinders being unprovided with the myelin sheath. The development of myelin corresponds to the acme of cerebral evolution, hence their absence in the new-born and their greater frequency, according to J. Engels, in the bodies of adults. For the same reason the *pes pedunculi* of the new-born *is gray instead of white. The unsimultaneous development of the medullary white in different parts of the brain is indeed a most important subject for searching study*" (Stricker's Collection, vol. ii., pp. 770–71).

[1] I refer here only to studies made on the human subject, when speaking of actual discrepancies.

[2] Plan of the Human Brain, page 42, foot-note. It may serve to show that the day of speculation as to this *terra incognita* of brain anatomy is far from waning, that while Flechsig suggests a possible vicariation of the cerebellum for deficiency of the intellectual organ *par excellence*, Starr, with all the well-established facts elucidated by Flechsig at his disposal, concludes that it is in part a centre connected with vegetative life (The Sensory Tract in the Central Nervous System, Alumni Prize Essay, College of Physicians and Surgeons, by M. Allen Starr).

[3] Lehrbuch der Gehirnkrankheiten, ed. 1., 1881. Not in American hands till 1883.

[4] Loc. cit., p. 52.

conclusions, as he supposes, very different from those of Wernicke and my own;[1] my own position having been to some extent misapprehended by Starr, as he has since recognized in a note to the *Journal of Nervous and Mental Diseases*, in which his article appeared. With regard to Wernicke, I think he has fallen into a similar misunderstanding. He says that his results of a study of cases is opposed to the course of the sensory tracts as described by Wernicke, for several reasons, among them, because "these tracts are supposed to leave the medulla and to pass by way of the cerebellum to the pons." The further text of his article shows that Starr attributes to Wernicke the view that *all* sensory tracts pass by way of the cerebellum, and *none* by way of the pons. In reality Wernicke's position is very conservative, he discusses the entire question, and concludes that there are several possible channels by which sensory paths may reach the cerebrum, which he details under the headings I. and II., A. (*a* and *b*), B. (*a*, *b*, *c*). Of these, all but the first are enumerated by Starr, who implies that Wernicke rejects the alternative under I., namely: a path of single decussation (running through) the most lateral portion of fibres of the lateral "motor" field of the tegmental part (of the oblongata and pons), then above the exit-level of the trigeminus in the neighborhood of the ascending trigeminus root, (situated) in the spinal cord, in the "lateral layer bounding the gray substance," (then) decussation in the gray substance immediately above the respective posterior roots.[2]

I do not think that the language of Wernicke on page 262, where he discusses his own and Kahler's case, necessarily implies the interpretation Starr has given to it. If so, it is difficult to see why Wernicke should enumerate the above tract in his conclusions. He simply discusses a number of "important considerations and doubts,"[3] which are encountered by him in his attempt to consider the tract mentioned as the one. In the very paragraph where he expresses these doubts he says that "there must be separate (distinct) sensory paths in the oblongata," a conclusion at which I arrived some years ago,[4] and which seems to me to-day to be the only one that can be harmonized with those facts stated in the introductory remarks of the present paper. Starr's conclusion as to the course of the tracts for tactile perception repeats the hypothetical tract deduced by Wernicke in very many particulars. The doubts which troubled Wernicke are based on facts which have not been disputed to this day. They are as much a subject for consideration now as then.

The collection of cases made by Starr is accompanied by the following conclusions (p. 61): "Those sensory impulses which have not decussated in the spinal cord cross the median line in the sensory decussation of the medulla, and pass upward through the interolivary tract to the lemniscus, in which they ascend to the internal capsule. These are the sensations included under the term muscular sense." This proposition would seem to be as well based as the dictum that lesion of the motor tract in the internal capsule produces contralateral paralysis. The cases of Kahler and Pick, Meyer, Senator, and my own, cited, prove that lesion of one interolivary layer produces contralateral ataxia; indeed, in my case the anatomical proof of the decussation—the degeneration crossing in the direction of functional involvement—was as complete as the clinical evidence. This fact is furthermore in harmony with a statement of Brown Séquard, that in his puzzling symptoms of spinal hemisection the muscular sense does not follow the rule of spinal decussation, but suffers on the same side with the motor function. If Ferrier's recent contradiction[5] of Brown-Séquard's theorem stands, then we are in the same quandary as before with regard to the alternative stated by Wernicke, that if the sensory paths *all* decussate in the oblongata, they must redecussate twice in the cord, if the facts of capsular and spinal hemianæsthesia are to be harmonized.

Fig. 5.

As far as the tract we are now considering is traced from the nuclei of Burdach and Goll to the anterior (cephalic) end of the pons is concerned, our knowledge is very satisfactory. Above this point it is involved in some obscurity. Flechsig believes that a part of the

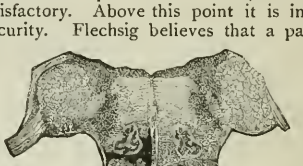

Fig. 6.

lemniscus, as far as I can glean, the one he believes to correspond to our tract, passes directly into the internal capsule. This would appear to be the simplest solution. Elsewhere he states that fibres derived from the putamen[1] and the nucleus caudatus, after coursing through the internal capsule, pass through the dorsal part of the pes pedunculi, being crowded against and pressed between the ventro-lateral processes of the substantia nigra. He considers it possible that this fasciculus is connected with the substantia nigra, for a large portion of it becomes lost here. The remainder he traces cordward as a ventro-medial accompaniment of the lemniscus layer, and supposes that it is ultimately united with the gray matter of the pons. This tract degenerates in the descending direction when diseased in the adult. Elsewhere[2] he speaks of the same fibres as intruding themselves between the lemniscus layer and the raphe "lower down," and as leaving the pes to enter the tegmentum. Certainly his first declaration, as to a probable connection with the nucleus pontis, is contradicted, not alone by the second statement, viz., that it passes into the tegmentum, but also by the course of the tract as indicated in his diagram, which is made to run quite parallel with his "interolivary layer," and into it.

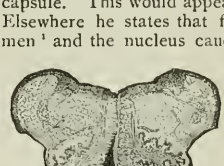

Fig. 7.

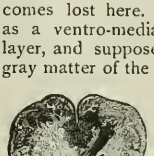

Fig. 8.

The interolivary layer of Flechsig is, according to him, the continuation of the interolivary layer upward. Two-thirds of this fibre system is represented in that part of the interolivary layer which is in immediate contact with the olives. He adds, with a query of his own, "and has no (?) connection with the upper pyramidal decussation." This query was certainly a saving afterthought. The secondary degeneration described

[3] "Wichtige Bedenken." "Bedenken" is best rendered as a mixture of "reflection" and "doubt," for which there is no accurate equivalent in English; it implies hesitation.

[4] Architecture of the Oblongata, New York Medical Journal, September, 1881. The view of separate tracts for muscular and tactile sense is expressed in this article, but has been much modified in detail since.

[5] He claims that the muscular seose path decussates in the cord.

[1] The outer of the three (or four, and in some subjects five) "articuli" of the lenticular nucleus.

[2] Plan of the Human Brain, p. 20.

in a case of pons lesion by myself appears to dispose of this question. In it the degeneration was limited to that very portion of the interolivary layer, and the corresponding half of the upper pyramidal decussation was almost entirely eliminated.

Another statement of Flechsig's demonstrates that he has confounded the relations of the two divisions he has made. He says the smaller division—that is, the part remaining of the lemniscus after the larger portion adjacent to the olive is subtracted—is connected with the upper pyramidal decussation, and that its fibres do not degenerate for any distance downward." Now, it is the very part which does connect with the pyramids, but which lies adjacent to the olives, which degenerates *downward* (cordward) for its entire anatomical extent, as shown in the diagrams and fac-similes on the opposite page. Flechsig is also wrong in asserting that the greater part of the lemniscus (two-thirds) degenerates downward,[1] giving, as he does, the impression that this is an invariable rule. In my case the *ascending degeneration* monopolized by far the larger *lemniscus field*, all of it, in fact, with the exception of that innermost portion which some authors fail to include in the lemniscus proper, and an outer part whose position is not well settled.

Monakow produced *descending degeneration* of apparently the same field which Flechsig terms inter-olivary layer, in the cat. As in my human case, this degeneration underwent a decussation, chiefly in the lower olivary[2] plane and passed into the nuclei of the columns of Goll, which, as in my case also, were atrophic. Monakow's description[3] of this tract, which degenerated after destruction of the parietal lobe,[4] following a course through the external and posterior nuclei of the thalamus into the dorsal part of the subthalamic region, corresponds more closely to the appearances found in my case than do any of Flechsig's delineations and declarations. The correspondence between the results obtained by the atrophy method in the cat, and previously by myself in a case of secondary degeneration, herein repeatedly referred to, are so close that I may be permitted to detail some anatomical facts observed in the lion, the dog, and the cat, in sections prepared by means of the bichromate of potash hardening, microtome cutting, and carmine staining methods, as bearing on the presumable course of this part of the lemniscus tract in man. The advantage of a study of these animals is that the pyramid, pons, and pes are small, and particularly that the pons fibres do not, as in man, crowd the tegmentum dorsad, compelling certain of its tracts to follow as arched a course as in man; this is a source of much confusion to the topographical anatomist.

In a section made flat-wise through the brain axis, that is, parallel to the basi-cranial ideal plane, in the dog, the intricate relations indicated in Fig. 10 are exposed.[5] In the latitude of the trapezium (23) a faint sagittal streak on either side indicates the interolivary layer (21), the oblongata portion of which is seen (27) mesad of the *dentoliva* (28). There appears to be a ganglionic interpolation between it and the major part of the lemniscus (26). Now, instead of sweeping to the side in the pons, to pass into the L-shaped lemniscus field of the mesencephalon, the interolivary layer is seen to occupy a distinct field, buried in the nuclear substance of the pons

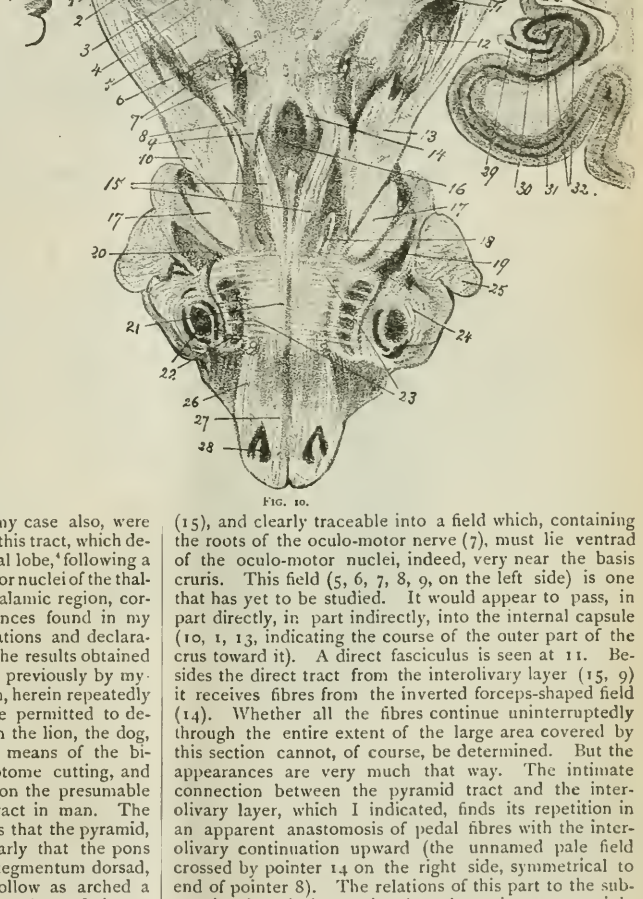

FIG. 10.

(15), and clearly traceable into a field which, containing the roots of the oculo-motor nerve (7), must lie ventrad of the oculo-motor nuclei, indeed, very near the basis cruris. This field (5, 6, 7, 8, 9, on the left side) is one that has yet to be studied. It would appear to pass, in part directly, in part indirectly, into the internal capsule (10, 1, 13, indicating the course of the outer part of the crus toward it). A direct fasciculus is seen at 11. Besides the direct tract from the interolivary layer (15, 9) it receives fibres from the inverted forceps-shaped field (14). Whether all the fibres continue uninterruptedly through the entire extent of the large area covered by this section cannot, of course, be determined. But the appearances are very much that way. The intimate connection between the pyramid tract and the interolivary layer, which I indicated, finds its repetition in an apparent anastomosis of pedal fibres with the interolivary continuation upward (the unnamed pale field crossed by pointer 14 on the right side, symmetrical to end of pointer 8). The relations of this part to the substantia nigra is interesting, but the main part certainly passes through without interruption.

In the human brain, owing to the causes mentioned, the relations are not so simple. The appearances are, however, against the view that the interolivary layer passes exclusively into the field known as the lemniscus; the bundle from the pes to the tegmentum appears to be, in part at least, connected with it. In Fig. 11, which represents a section taken in a plane, slightly raised dorsally in front, as compared with Fig. 10, the interolivary layer is shown in as complete a continuity as it can be, without preliminary distortion of the brain axis. It is here seen that the interolivary layer, beginning just above the pyramid decussation at *c*, passes on either side of the raphe (*d*, *c*, *b*, *a*) detaching (apparently) fibres (at 7 and 6), which, moving out more and more laterad (5), reach the lemniscus field of the mesencephalon (4). But the fibres

[1] Loc. cit., p. 26.

[2] In speaking of the olive, I refer to the olive *par excellence*, the one in the oblongata; the so-called "upper olive," I term the nucleus of the trapezium.

[3] Experimental Contributions to Our Knowledge of the Pyramid and Lemniscus Tracts, by v. Monakow, Correspondenzblatt f. Schweizer Aerzte, 1884, Nos. 6 and 7, per Mendel's Centralblatt, May 1, 1884.

[4] Not necessarily homologous with the same lobe in man.

[5] There is a comical resemblance between the figure when inverted, and the head of a bull or bear, and when upright that of an elephant. The former may facilitate a topographical understanding. The snout of the bull is the olivo-pyramidal region, the nostrils being represented by the main or dentate nucleus of the olive (28), the eyes with the lids are represented by the nuclei of the trapezium or superior olives (23, 22), the ears by the *pontis brachium* or middle cerebellar peduncle (25), and for horns, lovers of the fanciful may take their choice between 17 and 19. The bulk of the head comprises the trapezium and pons, the neck is equivalent to the mesencephalo-crural region.

hugging the middle line do not pass into this field at *a*, they dip ventrad apparently; this is the locality where so much confusion prevails, which can be cleared up by filling in the required gap with the tracts 9 and 14 of Fig. 10.

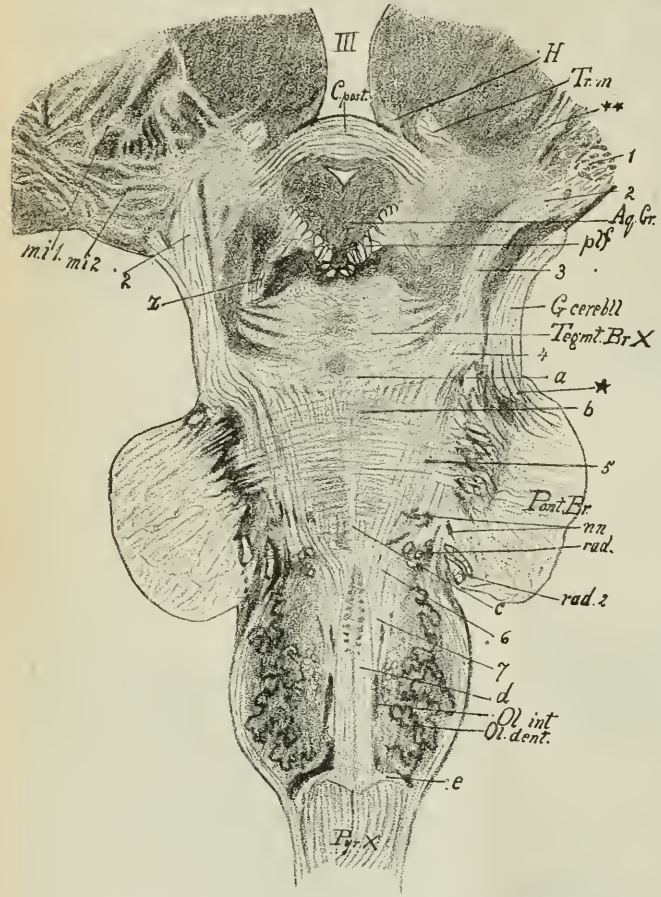

FIG. 11.—Section in Basilar Plane of the Brain Axis of a Syphilitic Subject. (Autopsy and case by Prof. James L. Little.) The numerals 1 to 7 relate to the lemniscus tracts in general; the letters *a* to *e*, to the mesal continuation of the interolivary layer, bundle from *pes* to *tegmentum* of Henle (see Part II.); *III*, posterior part of third ventricle; *C. post.*, posterior commissure; *Aq. Gr.*, gray matter surrounding the aqueduct; *H*, habennular bundle; *mi* 1 and 2, thalamic laminæ; **, unnamed tract, from analogy with 2 and 4 of Fig. 10, possibly the capsule seeking part of the interolivary (muscular sense) tract; *pf.*, posterior longitudinal fasciculus; *G. cerebll.*, Gratiolet's direct fasciculus from the cerebellum to the cerebrum; *, its cerebellar origin (nearly); *Tegmt. Br X.*, Wernekinck's commissure (?) decussation of *tegmenta brachium* (*brachium conjunctivum*); *Pont. Br.*, *pontis brachium*, middle cerebellar peduncle; *rad.*, roots of the seventh and eighth cranial nerves; *Ol. int.*, internal accessory olive; *Ol. dent.*, dentate or main olivary nucleus; *Pyr. X.*, decussation of true pyramids; pointer 5 is in the direction of the transverse pons fibres, a thin veneer of which has been cut.

The almost direct passage of the main part of the lemniscus toward the internal capsule is well seen at 2 and 1.

If my surmise as to the equivalence of the unnamed tract, indicated by the double asterisk, with those indicated by the numerals 2 and 4 in Fig. 10 be correct, it becomes comparatively easy to complete the channel of the muscular sense. In the accompanying section from a monkey (Fig. 12 [1]) the numerals 9 and 8 indicate this tract exposed lengthwise; its direction is clearly to the parietal lobe. It becomes apparent how Meynert could erroneously trace this bundle to the occipital lobes, in less fortunate sections, inasmuch as it closely skirts the optic radiation of Gratiolet. The direction of the main (lateral and middle) part of the lemniscus is indicated by the numerals 25, 27, and 28. If, as is surmised, the tract for muscular sense (9, 6) separate from the cutaneous tract (25, 27) in its course through the medulla and pons, becomes united to or intermingled with it in the thalamo-lenticular division of the capsule, we can readily understand why all qualities of sensation would be affected in capsular hemianæsthesia, while they may be separately involved in the pons and oblongata. The close proximity of the former and the motor tract 10 would be consistent with the frequently overlooked disturbance of the muscular sense in hemiplegia. The tract-course here supposed is consistent with v. Monakow's experiments, and justifies the designation of Rinden-Schleife (cortex lemniscus), which he has given the interolivary tract

As satisfactory as the picture of the interclivary layer is in sagittal sections taken through its pontine course, as difficult is it to identify every corresponding area of that course in transverse sections. In sagittal section, the stratum intermedium (interolivare) is a beautiful arched fasciculus, covering Gall's *ligne de separation* already referred to (Part II.). At one point it does not appear to adhere to that line, but to be broken up, and where not broken up to take a more dorsal course. This portion, however, resumes the characteristic relations in the caudal half of the pons. The deviation corresponds to a ganglionic intercalation described by Roller, which is reticular, like a trellis-work. It is found at the point where the tegmentum is most reduced in its dorso-ventral diameter (owing to the exclusion of the tegmenta brachium and the inferior cerebellar peduncles from this field).[1] In transverse sections at this level a distinct field is seen, dorsad of and encroaching on the trellis-work; it extends to the raphe and overlaps the mesal end of the horizontal lemniscus field; this is probably the (diverted) dorsal part of the intermediate tract.

Every specimen in my possession indicates that a large part of this fasciculus becomes lost in the substantia nigra. At the same time a portion continues directly forward as in the dog. This part has been regarded by Wernicke [2] as a bundle from the pes to the lemniscus. It is accurately represented in Figs. XIII., 50, 52, and 53 (*p*, *p'*), but there is a curious inconsistency. In Fig. 48 he represents this fasciculus as giving off the most anterior transverse pons fibres, as if it exhausted itself in their formation, while in the level above and below this one he has the fasciculus divided transversely and occupying identical situations. He has undoubtedly confounded it with another bundle in this section. This bundle, correctly named by Wernicke, lies on the latero-dorsal aspect of the prepontine fossa, where the pes is free of the pons, it occupies the slope on each side of the interpeduncular depression. As Wernicke in Fig.

[1] For this animal as well as the lion, I am indebted to Dr. Cooklin of the Central Park Zoological Department.

[1] The projection-system of the brain axis is reduced here, through the deflection to the cerebellum of certain tracts from above and below.

[2] Lehrbuch.

XII. (p. 89) terms a bundle occupying a corresponding situation the ansa lenticularis (Linsenkernschlinge), it is possible that through the intervention of this fasciculus

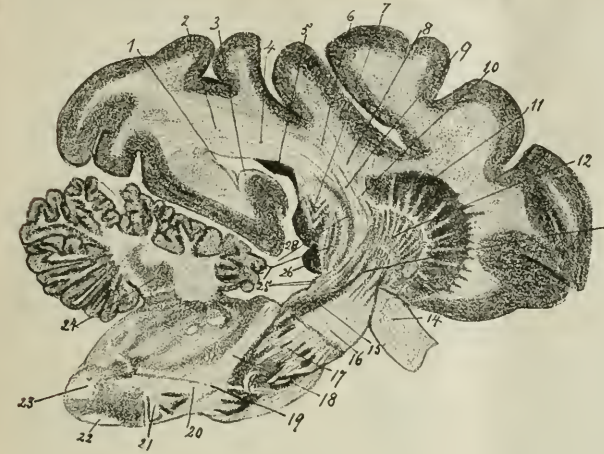

Fig. 12.—Section Diagonal to the Sagittal Plane, Deviating Laterad above, through a Monkey's Brain. (× 1¼.) 1, post-cornu; 2, 4, optic radiations of Gratiolet (hemianopsia tract); 3, cornu ammonis; 5, tail of caudate nucleus (*caudex corporis striati*); 6, 9, muscular sense tract (?); 8, 10, posterior part of voluntary motor tract (the reader must not be misled by its *apparent* relation to the posterior part of the lenticular nucleus, which is not touched in this section and extends, avoiding this plane, much farther back); 11, 12, lenticular nucleus (putamen and middle articulus); 14, optic chiasm; 18, 20, 25, lemniscus, fields; 22, direct mylo-cerebellar tract; 24, dentate nucleus of cerebellum; 26, geniculatum internum; 7, geniculatum externum; 27, radiations of lemniscus into thalamic laminæ.

it reaches the higher destination. The optical appearance of the two bundles in their designable course is different.

(To be continued.)

CORYZA VASOMOTORIA PERIODICA ("HAY ASTHMA") IN THE NEGRO.

With some Remarks on the Etiology of the Disease.[1]

By JOHN N. MACKENZIE, M.D.,

surgeon to the baltimore eye, ear, and throat charity hospital.

The absence of so-called "hay asthma" in the negro has been brought into prominence by recent writers on the subject, and notably by Beard, as an argument in favor of the important rôle which race is supposed to play in the etiology of the disease. The following case derives its peculiar interest from the fact that, so far as I am aware, it is the first recorded instance of the affection in a race in which the possibility of its occurrence has been denied.

J. M——, aged thirty-five, unmarried, a tall, well-proportioned, respectable colored man, came, September 6, 1884, to my clinic at the hospital to be treated for "hay asthma." His history may be briefly summed up as follows: He has always been remarkably healthy, with the exception of a tendency to catch cold upon exposure to the most trivial exciting causes. Ever since his earliest recollection, the emanations from hay have invariably excited a coryza of great severity, lasting from three to seven days and then subsiding. Handling hay at any season of the year, or even unpacking articles enveloped in straw, always bring on sneezing, lachrymation, flushing of the conjunctivæ, and obstruction of the nostrils. For the past four years has had an almost constant sensation of "stuffiness" in the nostrils, with dyspnœa on exertion accompanied by a slight post-nasal discharge, and the attacks of coryza have become much more frequent and have been associated with distressing asthma.

The attack is ushered in sometimes by a tickling or itching sensation in the upper and back portion of the throat and nose, sometimes by violent sternutation. The nostrils become suddenly obstructed, a profuse watery discharge is excited, the eyes become red, swollen, and painful, and the lids slightly puffed. There is always increased lachrymation. Cough is sometimes present, but forms an unimportant feature of the paroxysm. In a short while, generally in the course of an hour, the asthmatic symptoms supervene. The extreme dyspnœa thereby produced renders him perfectly helpless. The asthma is worse at night, so that during the period of his attack he gets very little sleep, the dyspnœa often amounting to orthopnœa. The latter is relieved after an hour or more by violent sneezing, followed by a copious watery discharge from the nose. After this he falls asleep, to be awakened in a short while by another attack of asthma, which is in turn relieved by sternutation. He sleeps habitually on his right side, with the head elevated. This state of affairs lasts from the second week in August to late in September, when the coryza and asthma disappear, leaving him in a state of nervous prostration and with a slight nasal discharge. During the period of "cold" the apex and sides of the nose frequently become excessively vascular, and the skin is cast off as the disease subsides. During the past four years, the paroxysms have been increasing in severity, the present attack having compelled him to give up his position as a waiter in one of the hotels of the city. The disease may come on at any season of the year, if he is exposed to its exciting causes, but he rarely suffers between April 1st and the second week in August. At the latter period he never escapes. Among the exciting causes in his case, apart from the emanations from hay, are exposure to sudden atmospheric changes, coal dust, the use of tobacco, the inhalation of tobacco smoke, and the greasy smell of the kitchen. The dust from cleaning various articles, dusting carpets, door-mats, etc., invariably provokes coryza. The odor or presence of flowers, light, and diet have no effect at any season of the year. He has never had any symptoms referable to a disordered nervous system before the appearance of the asthmatic feature of his disease. Since then has become restless and irritable and is subject to attacks of nervous debility.

The only relief he has ever gotten, apart from the natural termination of the paroxysm by sternutation, has been from the inhalation through the nostrils of the fumes of some proprietary pastils.

Physical examination.—No disease of lower respiratory apparatus. Simple congestion of nasal and lower pharynx. Posterior extremities of the lower turbinated bones engorged, swollen, bright red, and covered with a translucent film of mucus. Posterior nares symmetrical. Hypertrophic enlargement of the erectile tissue of the posterior part of septum on right side. Anterior extremities of inferior turbinated bodies slightly swollen, bright red, and present the appearance of two little rounded prominences jutting out from the outer half of the nasal floor. The interval between them and the middle is considerable, and the latter are remarkably prominent, running in an oblique direction from behind, upward and forward. Septum straight, face symmetrical. The mucous membrane covering the anterior end of the middle turbinated body especially swollen, but the swelling can be readily reduced with the probe, the action awakening no reflex.

Systematic exploration of all accessible portions of the nasal chambers with the probe gave rise to no reflex except at one spot. Along the inner edge of the left inferior turbinated body, about one and one-fourth

[1] Read before the Clinical Society of Maryland, October 3, 1884.

inch by measurement within the nostril, the *most exquisite paroxysm of asthma followed the simple contact of the exploring probe.* The sonorous and sibilant râles were loud enough to be heard in the adjoining room. The conjunctivæ became flushed, painful, and covered with tears, and a thin watery discharge accumulated in the nostrils. These symptoms lasted for a few moments and passed away, leaving the condition as described above.[1]

My views in regard to the predisposing and exciting causes of the disease popularly known as "hay asthma," have been given in a condensed form elsewhere,[2] and the design of the present article is to supplement these by calling attention to some additional facts derived from personal study of the affection.

While the majority of cases that apply for treatment come from the educated classes, and from those of fair intellectual development, it must not be forgotten that it is precisely this class that seek intelligent medical advice, or are likely to come within the range of circulars distributed by those investigating the complaint. Looking upon the disease as, to all intents and purposes, a coryza, generally dependent upon abnormal excitability of the vaso-motor centres, it does not seem to me justifiable to confine the operation of its causes within the limits of a particular century, or to explain its phenomena on the hypothesis of national or race peculiarities. I meet with it at all ages and in every condition of life, in private and in hospital practice. I find it more common among women than is generally supposed, and am inclined to think that the question of sex is one of unimportant etiological significance. I have twice observed the disease in several members of the same family, and it is possible that a peculiar excitability or deranged condition of the vaso-motor system may descend from father to son, and determine the appearance of the affection in the latter; but it is difficult to say how far the influence of inheritance, as originally suggested by Wyman, enters as a factor into its causation.

In the majority of cases that have come directly or indirectly under my observation, the paroxysms are induced by a variety of agencies differing entirely in their character and mode of operation. In others there is apparently only one exciting cause. The latter may be in operation only during certain periods of the year, or may provoke an attack, without regard to season, whenever applied.

It may be said, in general, that the exciting cause may produce its effect, (1) by direct or indirect (reflex) irritation of the sensitive nerves of the nasal mucous membrane; (2) through olfactory impression (so-called "idiosyncrasy" of olfaction); or (3) through simple association of ideas; or the same result may be brought about (4) by physical or mental overexertion, or (5) emotional excitement.

Typical paroxysms occur in some persons at any season of the year, from sudden changes in the temperature or from electrical disturbance of the atmosphere, and so far as my observation goes, a prominent position should be accorded to meteorological conditions among the exciting causes.

Pollen is only one of a host of exciting causes, and there is reason to believe that in some cases in which it is supposed to be the excitant, it has little or no influence at all. The paroxysm may be produced as a reflex phenomenon from irritation of a distant organ,[3] and a case has been brought to my notice by a distinguished medical friend, in which the ingestion of a few grains of quinia is sufficient to produce a group of symptoms which, if they were excited by smelling a rose, would be called "rose cold." More accurate observations are necessary to the formulation of definite conclusions concerning the occurrence of this disease in the inferior races. While it is doubtless true, that the physical and moral forces of civilization encourage its development in the higher walks of life, they probably do so only in so far as they predispose to abnormal excitability of the nervous system in general, or to catarrhal and asthmatic affections.

In the black race, the exquisite delicacy of the sense of smell, the prominent development of the turbinated bones, and the consequent increased amount of surface exposed, would seem to invite the paroxysm in those surrounded by the conditions that provoke it. I have several times met with reflected phenomena in the negro referable to disease of the nose, and belonging to the same category of reflex affections; and it is possible that a fair proportion of cases of the convulsive asthma which occur in that race may have a similar origin.

While the above case is the only instance of the occurrence of the disease in the negro that has come under my personal observation, it is quite possible that, if looked for, it may be more frequently found.

[1] The sensitive spot was destroyed by a stellate incision with the small knife of the galvano-cautery. On the night of the operation the patient had a slight attack of asthma, which passed off, however, in the course of an hour. For the next five days he enjoyed perfect immunity from the disease. He then went on a fishing expedition with a party of gentlemen, and the first night out contracted a violent cold in the head from sleeping on the damp ground, and with the coryza the attacks of asthma returned. At the present writing treatment has been suspended until the attack of coryza subsides.

DANGER FROM PLASTER-OF-PARIS JACKETS.

With a Description of the Woven-wire Jacket.

By SAMUEL W. SMITH, M.D.,

NEW YORK CITY.

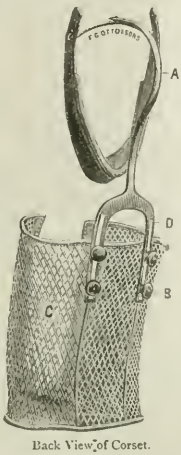
In the science of medicine, as in other sciences, there is a tendency to follow certain recognized plans or systems of procedure, to the ignoring of original methods, and a tendency to forget that while all may have advantages, and promise good, all must have in some case disadvantages that tend to evil. This fact has been forcibly impressed upon my mind in the use of the plaster-of-Paris jacket in cases of Pott's disease of the spine.

The following cases will illustrate my meaning:

Case I.—Daisie D——, aged seven. Born of healthy parents, her own health was good until she reached her fifth year, when it was observed that she constantly rested her head upon her hands when not at play. She soon became very irritable, and refused to play with other children. At this time she was taken to the family physician who discovered an angular curvature of the spine, including the last cervical and first and second dorsal vertebræ. In the course of time a Tiemann & Co.'s splint with jury-mast was put on. The child did well and returned to its amusements as usual. Within about a year the child had grown so much that the splint could not be worn without a slight change being made in it. At this time the patient came under my care for a bronchial affection, which disappeared after appropriate treatment of two or three weeks' duration. In accordance with the advice of friends she was taken by the parents to a surgeon of this city, by whom a plaster-of-Paris jacket was substituted for the Tiemann & Co.'s splint. For a day or two the child appeared to be quite as comfortable as with the former apparatus, but within a week I was again called to see her. I found her suffering from capillary bronchitis. The attendance of the surgeon who had put on the plaster jacket was requested by me, and he at once removed it. On the third day the little patient died of capillary bronchitis. My own opinion is, that the primary cause of death in this case was due to the sudden cooling of the body of the child which was effected by the hardening and drying process of the plaster composing the jacket.

Case II.—Nellie R——, fourteen years of age, from Connecticut. Came to the Demilt Dispensary in the spring of 1881, suffering from lateral curvature of the spine. Born of healthy parents; her own general health good; no bronchial disease. I put on a plaster-of-Paris jacket and ordered daily exercise with the pulley and chin support. In three weeks she returned to my office

suffering from a severe bronchitis, loss of appetite, and irritable cough. I removed the jacket, and in a few weeks the patient returned entirely recovered from the bronchial difficulty. I then applied a second jacket, doing so at my office, where the room was properly warmed to prevent the likelihood of "catching cold." In two months she returned and informed me that during all this time she had suffered from a troublesome cough; but so anxious was she to get rid of her deformity, that she had preferred to endure the cough rather than have the jacket removed! However, I removed it, and ordered a corset, made over a slight untempered steel frame, and covered with firm material, something after the plan of Professor L. A. Sayre's spinal wire corset. The corset was easily made by taking the removed plaster jacket and filling it with plaster prepared for the purpose. This gave me a complete cast of the deformity. The suspension treatment was still continued, and with the greater ease and comfort of the corset, my patient steadily improved. The bronchitis and cough disappeared in a short time.



Back View of Corset.

During my service at the Demilt Dispensary several other patients to whom I had applied the plaster jacket gave me the same kind of trouble; so that about two years ago I abandoned the use of it, excepting in such cases of Dispensary patients as were unable, through poverty, to pay for the corset. In all cases in which I was thus obliged to use the plaster jacket, I opened the front and so arranged it that removal at bedtime could be easily accomplished, as also the replacing of it before arising.

The corset which I have used instead of the plaster-of-Paris jacket can be made of any strong, pliable material, over the untempered steel frame; but that which I have more recently had made is of light tinned wire, interwoven in the iron frame, and shaped over the plaster cast of the deformed patient. Professor F. H. Hamilton's "Wire Gauze Hip Splint" suggested to me the use of the same material for my corset. It is easily arranged for the use of the jury-mast when needed, by means of screw loops on the two steel rods which give support to the back. The legs of the jury-mast having slits in them can easily be made fast by a screw.

In addition to the disadvantages of wearing a plaster-of-Paris jacket for consecutive months, alluded to above, it seems but reasonable to suppose that by this long-continued pressure of the chest walls, their natural growth should be stunted, their capacity for lung expansion much lessened, and a road laid out which may lead on to phthisis.

40 West Twenty-fifth Street.

Treating Tape-Worm with Chloroform.—Dr. L. E. Borcheim, of Atlanta, Ga., writes that he has treated two patients suffering from tænia solium, with chloroform, etc., according to the method of Dr. J. G. Brooks (Medical Record, Vol. 26, Nos. 4 and 11). In both cases he was unsuccessful. The patients complained of feelings of intoxication, the pulse rose, purging was brisk, but no tape-worm. On the other hand, Dr. N. S. Darling, of La Forte, Ind., states that he administered, after a fast of twenty-four hours, chloroform ʒ j., with castor-oil ℥ ij., to an adult male, with the result of expelling a tape-worm thirty-seven feet in length. The head, it is believed, was brought away with the mass.

A CURIOUS INJURY FROM A PITCHFORK.

By A. A. ELLIOTT, M.D.,
STEUBENVILLE, O.

On August 19th I saw, in consultation with Drs. G. A. Shane and J. F. Whittaker, the following case:

William P——, a farmer, thirty years of age, weighing about one hundred and fifty pounds, muscular development good, while sliding from a hay-mow came in contact with a pitchfork which was standing tines upward against the contents of the mow. One of the prongs penetrated the right hip, at a point behind and on a level with the greater trochanter, and broke off close to the socket.

Found him lying on the porch of the house, to which he had been taken, complaining of severe pain in his hip, abdomen, and back, and greatly frightened. On examination we found a penetrating wound in the right hip, and just beneath the surface a metallic substance was detected and removed, being the lower portion of the fork-tine, one and three-quarter inch in length, and fitting accurately at its larger end, the stump remaining on the handle. Measurement of the remaining tine showed it to be thirteen inches in length, leaving about eleven inches yet to be accounted for.

The patient complained greatly of his back, and a view of it disclosed an enlargement on the right side of the spinal column in the lumbar region, which was exquisitely sensitive. This apparent swelling showed no bruising or evidence of recent contusion, and inquiry elicited no history of its existence previous to this time.

We proceeded, under an anæsthetic, to further explore for the missing steel, and found the direction of the wound to be upward, inward, and forward, and succeeded in following its track for about five inches with a probe, but without detecting any foreign body, nor could we by enlarging the wound and making deep pressure determine its presence.

He was allowed to come out from under the influence of the ether in order to get the benefit of his sensations under our manipulations, and his thigh was flexed on his abdomen, deep pressure again made, together with abduction and adduction of the thigh, producing no increase of pain in any region.

After several hours he was again etherized, and the most critical examination made in the wound and by the rectum, and the swelling on the back laid open and thoroughly explored; all to no purpose, and the wounds were left unclosed and dressed with water dressing.

The case resolved itself into the following conditions: 1. Head of the fork-tine penetrated and lodged in the body of the man; if so, could it be removed? 2. If in his body, had it penetrated the pelvic cavity or was it buried in the dense muscular structure of the hip? 3. Could it be possible that the first portion of the tine had, by the force of the falling body, broken off and by its elasticity flew away, and, the fall being unbroken, the fork again came in contact with the body and penetrated with the remainder? These questions were taken up and concluded upon: 1. There was no positive evidence furnished by the examination that the tine was lodged in his body, and, were it positive, an operation for its removal would involve a dissection of the muscular structure of the hip, and perhaps an opening of the abdominal cavity, both under the circumstances unjustifiable operations. 2. The abdominal pain was taken as suspicious at least, and the bladder and rectum had not as yet acted, leaving their injury in doubt. 3. The possibility of this condition was acted upon, and the barn most thoroughly searched for the missing tine, but it was not found.

We now concluded to leave the case to nature, and the patient went on doing well, his bowels and bladder performing their functions normally. After a few days, when his fright had subsided, he remembered that the injury to his back was of long ago, and always gave him trouble, and that his abdominal pain had preceded the

injury several days and had been accompanied with diarrhœa, which continued. The wound in the back healed kindly, but the one in the hip continued to discharge profusely, and in the fourth week the whole limb became swollen, and later fluctuation was detected below the sore, which increased in size and extended down the posterior aspect of the thigh, and on October 1st, forty-three days after the accident, it (the tine) was removed, large end first, from the upper portion of the popliteal space. It was eleven inches in length.

The tine was evidently lodged either in the hip or had penetrated the pelvis, the heavy end being dependent, and the muscular action produced by the patient's walking across the floor daily caused it to descend and appear as described.

Since its removal he is doing well, and the indications are that he will make a good recovery.

SOME REMARKS ON THE ASSOCIATION OF TUBERCULOSIS AND ACUTE PNEUMONIA.

By EDMUND C. WENDT, M.D.,
CURATOR TO ST. FRANCIS HOSPITAL, NEW YORK.

THE highly interesting case of tuberculous pneumonia, reported by Dr. Kinnicutt in the last issue of THE RECORD, prompts the writer to offer a few remarks on the synchronous occurrence of tuberculosis and pneumonia, particularly so as a case came under his observation four years ago, which was, in some respects at least, similar to the one observed by Dr. Kinnicutt. The writer considered it at the time a rather puzzling instance of rapidly fatal croupous pneumonia, of an atypical kind. Having occurred before the era of the bacillus tuberculosis and the pneumonia-micrococcus, it will scarcely seem, in the light of our present knowledge, or at least widespread belief, a case observed with sufficient scientific accuracy to warrant any concise deductions. But it should not be forgotten that, despite the rapidly progressive researches of positive experimental pathology, the entire subject of pneumonia, and for that matter of tuberculosis as well, is still a debatable one.

The writer's case, then, is to be regarded merely as a casuistical contribution to a subject of universal interest to the profession in the past, the present, and, it is to be hoped, the future.

Quite briefly stated the case was as follows: A. M——, male, aged thirty-six, married, the father of healthy children, himself the child of healthy parents, was seized with a rigor on a Monday, in March, 1880. He positively denied any previous serious illness, but admitted a tendency to "take cold" easily during changeable weather. He also stated that he had lost one sister from phthisis, at the age of twenty-two. Soon after the chill the patient developed the signs of croupous pneumonia on the right side, which soon spread throughout the entire middle and lower lobes. It was thought to be even encroaching on the upper lobe, when, on the third day, after the rigor had marked the incipience of severe illness, he suddenly died. Clinically the unusual signs had been an excessively high temperature (106⅘° to 107° F., in the rectum), associated with a pronounced typhoid condition. On the last day of his illness the patient also became intensely jaundiced.

At the autopsy the right lung was found hepatized in the middle and lower lobes. The hepatization, however, was grayish only in a few places, the prevailing color being a dark maroon. In the upper lobe, there was merely moderate congestion, some firm old pleuritic adhesions, a few slate-colored nodules with chalky centres, and a rather abundant crop of miliary tubercles. Besides this there were in both lungs quite a number of purulent foci, resembling the well-known multiple abscesses of pyæmia.

The left lung was congested, œdematous, and showed in its upper lobe a condition quite similar to what obtained on the right side, except that there were relatively fewer miliary tubercles and purulent collections. The latter in no instance exceeded in size that of a cherry-pit. The abdominal organs were in general much congested, especially the spleen, which was soft, large, and pulpy. The liver was found in the first stage of icteric hepatitis. The intestines were only moderately hyperæmic, otherwise normal. The common bile-duct was easily pervious. The brain was not examined. There were no miliary tubercles in any other organs, save those already mentioned, viz., the upper lobes of both lungs.

The questions that suggest themselves in this case, as well as in the one reported by Dr. Kinnicutt, are these: Was there a latent unrecognized tuberculosis upon which, as a suitable soil, a fatal croupous pneumonia became engrafted? or was there rather a primary lobar pneumonia, that afforded a fertile soil for the rapid development of acute tuberculosis? Without stopping to weigh arguments pro and contra, the writer would simply state his belief that in his own case the tuberculosis preceded, for weeks or months, the pneumonia; but that the latter would not have proved so rapidly fatal without the coexistence of the former. In Dr. Kinnicutt's case the sequence of events seems less clear. And it is much to be regretted that the microscopical examination of the sputum failed to make matters any clearer.

One thing may be learned from these cases. If croupous pneumonia is an infectious disease, caused by the invasion of a specific micro-organism, and if pulmonary tuberculosis similarly depends upon the entrance into the lungs of peculiar bacilli, then it follows that the growth and multiplication of these two typical and vastly dissimilar varieties of germs within the same organ, so far from being mutually antagonistic, may be reciprocally stimulating, and thus prove doubly dangerous to the host carrying the parasites.

In conclusion, the writer may be permitted to succinctly refer to a case of so-called "mixed infection through tubercular bacilli and pneumonia-micrococci," which was recently reported by Dr. Samter (*Berliner Klin. Wochenschrift*, June 23, 1884), and which seems to have escaped Dr. Kinnicutt's notice.

A weak and marantic-looking old man, aged sixty-five, was admitted to the Posen hospital on March 13, 1884. The patient had a slight, innocent-seeming cough, and a physical examination led only to the diagnosis of senile bronchitis. The patient improved visibly at first. But on April 19th he began to complain of great weakness, and showed an increased tendency to cough. His temperature, however, was below the normal. The scanty viscid sputum resembled somewhat that of ordinary lobar pneumonia. Microscopical examination, however, elicited the interesting fact that, in addition to the abundant presence of tubercle bacilli, the sputum contained a few of the characteristic micrococci of pneumonia. The physical signs of the latter affection subsequently became more marked, and the patient died in a few days from heart-failure. From the record of the post-mortem examination the following points, having a direct bearing on the subject under discussion, may be cited: In the apex of the left lung there were some old cheesy deposits, the entire right lung was intensely congested and in the first stage of pneumonia.

Scattered throughout all the lobes of this lung there was found an abundant crop of recent miliary tubercles, but not a single cheesy or purulent mass was discoverable in that lung. In the small intestine numerous ulcers existed, but there was no evidence there of miliary tuberculosis. It would seem, therefore, that this case resembled my own in several important respects. Dr. Samter is inclined to believe that his patient had latent tuberculosis; and further, that a sudden invasion of the specific germs of pneumonia wrought such changes in already damaged lungs that, an acute miliary tuberculosis was lit up where before there had only existed the slowly smouldering process of chronic tuberculosis.

In the light of the experience of his own case, the writer would fully concur in the above opinion.

102 EAST FIFTY-SEVENTH STREET, October 14, 1884.

Progress of Medical Science.

Adynamic Dilatation of the Stomach.—Dr. Enrique de Argaez has lately published a monograph on the above subject (Paris: Asselin & Co., 1884), which embodies a few novel points touching the pathogenesis and treatment of this interesting disease. In typical cases the author has usually found, on inspection, abnormal prominence of the epigastrium, and, more rarely, visible peristaltic movements of the stomach. The varying quality of resonance obtained by percussion over the colon, the small intestine, and the stomach, enables the observer to define the boundaries of the dilated organ. Succussion yields a characteristic sound, due to the simultaneous presence of gas and liquid in the stomach, and sometimes a metallic tinkling. M. Germain Sée, in whose service, at the Hôtel-Dieu, most of the cases observed by Dr. de Argaez were observed, finds proof of the existence of adynamic dilatation in the presence of gastric resonance at a distance greater than twelve or fifteen centimetres beyond the left mamillary line, or the presence of the gastric succussion sound six hours after eating. Under the head of symptomatology the familiar phenomena of epigastric pain, flatulence, emesis, and constipation are described. The principal causes of the dilatation are general weakness, disturbed local innervation, and excessive ingestion of aliment. The differential diagnosis involves the exclusion of gastralgia in ataxic patients, whose stomachs are not, however, found dilated, and of gastric ulcer. In the latter disease, blood, either pure or partially digested, and presenting the familiar coffee-ground aspect, is often present. This feature is always absent in atonic gastric dilatation. Other diseases to be excluded are alcoholic gastritis, fibrous stenosis of the pylorus, and carcinoma. In pyloric stenosis, whether of a benign or of a malignant character, the entire contents of the stomach are rejected by vomiting, which is not the case in adynamic dilatation. Under the head of treatment the author suggests a diet calculated to leave no undigested residue in the stomach, such as eggs, and tender meats, moderate exercise, gentle laxatives, and the use of Kussmaul's pump and Fancher's siphon-tube, to evacuate the distended stomach. The gastric pain is best relieved by chloroform, administered in small doses by the mouth, and by the continuous galvanic current. The author is in the habit of placing the positive pole at the centre of the epigastrium, and the negative over the sternum. The current is allowed to pass ten or twelve minutes at each sitting.

Why Negroes are Black.—Surgeon-Major Alcock has contributed to *Nature* a communication on the reason why tropical man is black, in which he suggests that, as in the lowest animals pigment-cells placed behind a transparent nerve-termination exalt its vibration to the highest pitch, the reverse takes place when, as in the negro, the pigment-cells are placed in front of the nerve-terminations, and that the black pigment in the skin serves to lessen the intensity of the nerve-vibrations that would be caused in a naked human body by exposure to a tropical sun. In fact, he thinks that the pigment plays about the same part as a piece of smoked glass held between the sun and the eye.

The Treatment of Psoriasis.—In the treatment of psoriasis, Professor Neumann, of Vienna, recommends arsenic in the form of the so-called "Asiatic pills," which are composed thus: Arsenious acid, gramme 1.0; black pepper, grammes 5.0; acacia gum, gramme 1.5; with a sufficiency of distilled water. The ingredients must be thoroughly pulverized and mixed, then enough gum arabic must be added to make two hundred pills. Each pill contains 0.005 gramme of arsenic. These are to be taken each day at first, and gradually increased till ten or twelve are taken. The soft-soap course, as an external remedy, in the form of the "Pfeuffer'schen Cyclus," is strongly recommended in cases of universal psoriasis, and is thus carried out: The patient, undressed, is laid between blankets and is rubbed twice a day for six days, and once a day for three more days, with the ordinary soft soap, one hundred grammes being used each time. The rubbing is conducted in such a manner that the whole of the affected skin is well rubbed each time, and, at each application, a fresh portion is rubbed in with a hard brush in such a manner that the surface commences to bleed. The patient remains in woollen cloths night and day, and on no account is bathing allowed till the fourteenth day, and the longer this is delayed the more easily will the dried skin and soap be separated, and the less pain and sense of stretching will be experienced. In case the bath is taken too early, the skin will feel too short and tight, movement will be difficult or impossible, and rhagades are very likely to occur.

Essential Anæmia.—Dr. Rosenbach, of Breslau (*Deutsche Med. Wochenschrift*), points out three characteristics of this disease. 1. It recurs at certain seasons of the year, so that we can distinguish a spring, a summer, and an autumn form. Cases occurring in winter are extremely rare, and those belonging to the height of summer seem to be the most severe. 2. A peculiar craving for acids is displayed by the patients, which must not be supposed to indicate merely a deficiency of hydrochloric acid in digestion, as any other acid, and even fresh fruit, may supply the want. The desire for acids ought to be gratified, as it is the assimilation of the patient that is at fault, and the organism instinctively demands what is needed. 3. Instead of feeling strongest in the morning, the patients are at their best in the late afternoon and evening, or sometimes even far into the night. Their desire for food follows the same rule, and it is best to let them eat at the times when they feel most appetite, irrespectively of ordinary meal times. It is also of no use to try to ensure brightness and freshness in the morning by making them go early to bed, as they do not sleep until their time of feeling strong has passed off. They ought to be as much in the sun and fresh air as possible, but ought not to fatigue themselves with walking. The anæmia of puberty is not included in these remarks. Dr. Rosenbach has found that the prognosis of the cases of essential anæmia is more favorable when the weakness and want of appetite are periodical, than when the patients are always tired, and refuse all kinds of food alike.

Medicinal Treatment of Habitual Constipation.—Dr. Mortimer Granville, in the *British Medical Journal*, gives three prescriptions for habitual constipation. Where there is a lax and torpid condition of the muscular coat of the intestine, the following is recommended: ℞. Sodæ valerianatis, gr. xxxvj.; tinct. nuc. vom., ʒ j.; tinct. capsici, ♏ xlviij.; syrupi aurantii, ʒ jss.; aq. ad ʒ vj., ʒ ss.; water half an hour before meals. Where there is a deficiency of glandular secretion throughout the intestine the following is useful: ℞. Aluminis, ʒ iij.; tinct. quassiæ, ʒ j.; infusi quassiæ, ad ʒ viij.; ʒ j. after meals. A third form of constipation, which depends chiefly on interruption of the natural habit of periodic discharge, is benefited by directing a regular attempt to go to stool, and to take the following draught the first thing after rising from bed: Ammon. carb., ʒ j.; tinct. valerianæ, ʒ j.; aq. camph. ad ʒ vj.; take a sixth part as directed.

Generalized Sarcoma of the Skin Cured by Subcutaneous Injections of Arsenic.—Generalized sarcoma of the skin occurs very rarely. Professor Köbner's patient (*Berliner Klinische Wochenschrift*), was a girl eight and a half years of age. The tumors, which were exceedingly numerous, existed over the whole surface of the body, except the nose and abdomen. They were bluish-red in color, and mostly of the size of a lentil to a split pea. They were hard and almost painless on pressure. The larger ones were of the size of a haricot bean. The lymphatic glands were swollen, and the liver

and spleen were slightly enlarged. There was no fever, but a feeble appetite and generally defective nutrition. The diagnosis was confirmed by an examination of two tumors which were excised for that purpose. The treatment adopted was subcutaneous injection of Fowler's solution of arsenic, diluted with two parts of distilled water to one of the solution. A dose equivalent to two and a half to four drops of Fowler's solution was injected daily; and between September 12th and December 9th, eight grammes of Fowler's solution had been injected. It had been necessary to occasionally suspend the injections, so that in three months only fifty injections had been made. From December 10th the dose of Fowler's solution was raised gradually to nine drops (diluted always in proportion). The result of the arsenical treatment was the gradual dispersion of the tumors and the diminution of the enlarged lymphatic glands. Pigmented spots existed for some time over the seat of the tumors, and in November (1882) the skin had become pliant and smooth. Only on the legs were there some small papules of lichen pilaris, and a very few similar papules on the arms. All the cicatrices had become pale, and on the limbs in particular a great number had entirely disappeared.

Warts.—In a course of lectures on dermatology, reported in the *Medical News*, Dr. Duhring says that verrucæ, or warts, either hard or soft, consist of variously sized and shaped papillary formations. *Verruca vulgaris*, or common wart, occurs about the hands, especially on the fingers. *Verruca plana*, or flat wart, is found on the back and about the shoulders. *Verruca filiformis*, consisting of a thin thread-like formation, is encountered on the eyelids and neck. *Verruca digitata*, a broad excrescence with finger-like processes springing from the borders, is found upon the scalp. *Verruca acuminata*, also called cauliflower excrescence and venereal wart, is a pinkish, violaceous, or bright-red fleshy vegetation occurring usually about the genitalia of either sex, and often accompanies venereal disease, being caused by purulent secretion or excessive heat and moisture. It may also occur independent of any venereal disease. It takes on various forms, and, as a rule, appears like the head of a cauliflower or a cock's comb. It consists of a proliferation of the epidermis, the development being rapid; the papillæ of the corium and the corium itself are also greatly hypertrophied, and the blood-vessels dilated, rendering the growth exceedingly vascular. The most satisfactory treatment of these growths is excision, and cauterizing their bases. The galvano-caustic ligature, chromic or nitric acid, or acid nitrate of mercury may be used. The oleate of arsenic is also said to act very well. In the treatment of venereal warts astringent lotions together with some dusting powder are highly useful. The writer has employed with satisfaction the method of touching these warts with nitrate of silver and covering with absorbent cotton.

Chronic Intestinal Catarrh.—Professor Nothnagel, at a recent meeting of the Royal and Imperial Society of Physicians at Vienna (*Wiener Med. Blätter*), spoke on the subject of chronic intestinal catarrh, which he said had been but little mentioned in text-books. There is also no explanation given, in physiological manuals, of the fact that healthy individuals have generally only one stool in the twenty-four hours. Nothnagel thinks that no explanation can be given, but that it is one of those arrangements, depending partly on the anatomical relations of the parts, and partly on innervation, for which we cannot account. Chronic intestinal catarrh may be considered to be present when mucus appears in the motions, although the absence of mucus must not be regarded as conclusive evidence against the existence of catarrh. Nothnagel divides the cases of chronic intestinal catarrh into four classes: 1. Those patients who have a stool every second or third day, often produced artificially; this is the type of primary chronic catarrh of the large intestine, and depends, according to Nothnagel, on diminished anatomical activity of the ganglion-cells. 2. Cases where a stool is passed daily, but each time thin, pulpy, and mixed with mucus. 3. Cases with irregularity in the state of the bowels, sometimes constipation, sometimes diarrhœa, and sometimes an alternation between the two; the diminished activity of the nerve-cells explains the constipation, and the irritation of the fæces causes eventually the diarrhœa, which may also be excited by a very small error in diet. 4. Cases with continued diarrhœa. Here, however, chronic ulceration of the bowels must be distinguished from catarrh. Where diarrhœa is present without ulceration of the large intestine, Nothnagel has always found an affection of the small intestine as well. When the food does not undergo its normal changes in the small intestine, it acts as an irritant on the mucous membrane of the colon, and causes the diarrhœa. Some patients have a stool after each meal, some after a mid-day meal only, and some after an evening meal only. Nothnagel would explain this by referring it to nervous influence.

Freckles.—Freckles, or lentigo, may sometimes be made to disappear by an application of citrid acid night and morning. The method employed by dermatologists, and attended with considerable success, is to apply a solution of corrosive sublimate, one to three grains to the ounce of water, or emulsion of almonds night and morning. Dr. Duhring reports the latter as the most satisfactory, and advises its application until a slight amount of desquamation takes place.

Loosening of the Teeth.—Dr. Sewill, *British Medical Journal*, alludes to a disease which appears to be on the increase at the present time, and is characterized by a chronic wasting of the alveoli. The symptoms commence with inflammation of the free edge of the gums and the alveolar periosteum. The gums and alveoli slowly waste until the teeth are lost. The teeth are commonly of good structure and free from caries. There is in many cases deposits of tartar on the denuded surface of the root, and beneath the swollen and loosened margin of the gums. As a rule, several teeth are affected at the same time. The disease commonly shows itself about middle life. It sometimes accompanies diabetes, and also gout, and cases of debility and anæmia. The treatment consists in periodically removing the tartar, and swabbing the necks of the teeth beneath the loosened gums twice a week with pure carbolic acid.

Foreign Bodies in the Bladder.—In the "Mittheilungen aus der Chirurgischen Klinik zu Tübingen" is contained a paper on foreign bodies in the bladder, based on thirteen cases that have been treated in the Tübingen clinic in the course of the last thirty years. The term foreign body is used in a restricted sense, so as to exclude stone and such bodies as are formed within the organism. In by far the most cases the foreign body enters the bladder by the urethra. According to the statistics on this subject published in 1856 by Denucé, of Bordeaux, males and females constitute the subjects of this injury in almost equal numbers. In males, the foreign bodies are most frequently pieces of stalk or straw, wire, lead-pencil, and in females any of the different forms of needle and needle-case. The female patients are for the most part young, while most of the men are advanced in years. In six of the thirteen cases recorded by the author of this paper, the foreign body had passed into the bladder by the urethra. The patients in three cases were males, and aged respectively, forty-five, forty-nine, and fifty-four. Of the three females one was aged sixteen, one twenty-four, and the last twenty-five. A much smaller group is that of cases in which the foreign body consists of a broken and detached piece of some surgical instrument, as, for instance, a catheter, bougie, or sound, a lithotrite, caustic-holder, etc. Catheters of German-silver become very fragile after having been kept long, and ought not then to be used. Of elastic

catheters and bougies, Nélaton's catheter of vulcanized caoutchouc, after it has been kept long unused, becomes extremely fragile, while the ordinary elastic bougies become dangerous only after frequent use and prolonged retention in the bladder. Gutta-percha catheters, it is pointed out, are particularly dangerous. In most of the cases of this group the accident is owing to a fault rather of the patient than of the surgeon, and is the result of too frequent and prolonged use in catheterization of a worn-out instrument. The author's list includes five of such cases. In two instances the foreign body was the end of a metal catheter, and in the other three the end of an elastic catheter. The second way in which foreign bodies may reach the bladder is through a wound in the wall of this organ. The injury in such cases is either a penetrating or a gunshot wound. The penetrating wound through which the foreign body is passed is usually caused by some blunt instrument driven into the bladder from the perineum or anus. The retention of foreign bodies in the bladder occurs much more frequently after gunshot wounds. Of 285 cases of gunshot wound of the bladder collected by Bartels, 81 were complicated by retention of foreign bodies, consisting of portions of the fire-arm, or a fragment of bone, or a small portion of the clothing. Associated with the above injuries are those rare instances of ruptured bladder complicated by fracture of the pelvis, in which one or more loose fragments of bone are driven into the vesical cavity.

The third and least frequent way in which a foreign body can reach the bladder is through a pathological communication between the bladder and neighboring organs. The foreign body in such cases is usually something that has been swallowed, and has ultimately passed into the bladder from the ileum or rectum after adhesion and ulceration of their walls. By perforating ulceration, also, fœtal remains of extra-uterine pregnancy, sequestra from necrosis of the pelvis, and the contents (teeth, hair) of dermoid cysts of the ovary, have penetrated into the bladder. The foreign body is seldom expelled spontaneously by the urethra. Of 391 cases of foreign body in the bladder collected by Denucé, 13 only terminated in this way. In 2 of the 13 Tübingen cases there was a spontaneous discharge. The foreign body in one case was a long piece of metal catheter which had been four weeks in the bladder, in the other a straw. The foreign body, after prolonged detention in the bladder, becomes invariably incrusted with lime-salts, and may form the nucleus of a vesical calculus. Small and round bodies are soon completely incrusted, while long thin bodies are incrusted only in the middle, and are quite free at their ends. If a fragile body, a straw for instance, be broken up in the bladder, each of the fragments may form the nucleus of a distinct stone. The rapidity of the incrustation and the size of any calculus that may be formed depends on the nature of the substance forming the nucleus. Vegetable material becomes rapidly incrusted, and of hard materials silver and gold and glass are less readily incrusted than iron. Beyond this incrustation and formation of stone, the presence of a foreign body in the bladder very seldom gives rise to any special complication. In six only of the many cases collected by Denucé was death due to the direct action of the foreign body on the wall of the bladder. Some few instances have been recorded of the foreign body in the bladder of the female having penetrated into the vagina. The surgeon having assured himself of the presence of a foreign body in the bladder, it becomes very necessary for him, before deciding as to the means of removing it, to make out its size, form, consistence, position, and mobility. This may be done by digital exploration from the rectum, by bimanual examination by the rectum and anterior wall of the abdomen, and by the use of lithotriptic instruments. The endoscope, Dr. Knöller thinks, is not likely to prove of much service in these cases. The last and most difficult problem is the removal of the foreign body in the readiest and least dangerous way. If the body be of small size, and have not been long in the bladder, the surgeon may await for some time the chance of its being passed spontaneously with the urine. To favor this, a large thick bougie may be passed into a distended bladder, and then withdrawn so as to allow the urine to rush out in a full stream. Extraction by the natural passage is indicated when the circumference of the foreign body does not exceed the calibre of the urethra, and when it can be broken up within the bladder. Since the introduction of lithotrity, and with the progressive improvement in the instruments used in this operation, the extraction of the foreign body by lithotomy has been less frequently performed. The statistics of Denucé show that, while before 1830 extraction was performed in 27, and lithotomy in 100, out of 127 cases; since this year, out of 122 cases, extraction was practised in 101 and lithotomy in 21. In dealing with a foreign body in the bladder of a female, Dr. Knöller would advocate forcible dilatation of the urethra, introduction of the finger, and extraction by means of slender forceps. —*London Medical Record*, August 15, 1884.

Treatment of Acute Inflammation of the Knee-Joint.—Dr. Barwell draws attention to a method of treating severe inflammations of joints, and more especially those of the knee. In a sprain or wrench of a previously healthy joint, a severe attack of synovitis follows, with pain and swelling, but if dislocation takes place, no such symptoms follow, for the torn and synovial membrane permits the hypersecretion of the inflamed membrane to drain away, and thus relieve the tension. Acting on this doctrine, the method adopted by the author is as follows: Suppose the knee to be the injured joint, it is to be enveloped in a broad bandage of elastic webbing; or, if that be at the time unattainable, an ordinary calico bandage will answer the purpose, care being taken to leave between two of the turns a little interval on the inner side on a level with the upper margin of the patella. At this point there is passed into the joint a tubular needle, thoroughly cleansed and asepticised. The fluid runs away as a rule easily, and when the flow has ceased the needle is withdrawn, the puncture covered with strapping-plaster, made adherent by spreading on it turpentine (a potent aseptic), and this is to be painted over with collodion. Pressure by means of strapping-plaster must then be applied and the limb placed at rest on a splint for a few days. Dr. Barwell strongly urges that, in all cases, joints which show evident marks of tension should be evacuated in the above manner. Four cases are cited in which puncture was performed, the results being that in a few days the patients were convalescent.—*London Lancet.*

Homœopathy and the Treatment of Dysentery.—Dr. D. A. Baldwin, of Englewood, N. J., writes us concerning the method of treating dysentery with small doses of corrosive sublimate, as recommended again recently by Dr. S. B. Childs, Medical Record, August 23d. He says: "'Hull's Jahr,' for thirty years a leading manual of homœopathic practice, gives, under treatment of dysentery, mercurius bichlo. for painful bloody stools, and colocynth for the griping pains and tenesmus. The editor says: 'A successful procedure in our practice is the alternate administration of colocynth and mercury for many forms of dysentery. Colocynth first, trit., alternate with the mercury, when the griping pains and tenesmus are intense.' Every work of homœopathic practice published since recommends the same." Dr. Baldwin makes the extraordinary charge of "gross plagiarism," based upon the above. The charge, however, will fit better against Jahr. At any rate, mercury in small doses was recommended in Trousseau's "Treatise on Therapeutics," and was used more than thirty years ago by Leclerc.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, October 18, 1884.

THE FINAL REPORT OF THE COLLECTIVE INVESTIGATION COMMITTEE ON ACUTE LOBAR PNEUMONIA.

We have received the second volume of the "Collective Investigation Record," edited by the Collective Investigation Committee of the British Medical Association. It is larger than the first volume, and distinctly superior to it in the value of its contents. These relate to the subjects of acute pneumonia and puerperal pyrexia. The report on pneumonia supplements the preliminary report upon this subject made in the previous volume. At that time the Committee had received only 350 returns, while the present volume contains the analyses of 715 more, making 1,065 cases in all. Of this large number it was found that the returns in fourteen cases only were defective. There was left, then, an unprecedentedly large mass of data upon which to base conclusions. Nevertheless, the committee in their final summing up of results is wisely cautious in estimating the value of the inferences drawn. A good deal of the report has, as is admitted, only a negative value; while many of the points elicited were already known. It could hardly be expected, indeed, that any extraordinary facts should be brought out regarding a disease which has for centuries been tirelessly watched by so many competent investigators.

There are, however, some facts of fundamental importance presented, as well as many minor details of considerable practical interest.

The value of the Committee's report is much enhanced by several original communications upon the subject of the alleged zymotic and infectious nature of pneumonia. Dr. Octavius Sturges presents a concise and lucid historical paper upon epidemics of pneumonia in Great Britain. Dr. Sidney Coupland contributes a still more elaborate article upon foreign epidemics. A report of two epidemics of pneumonia in the Punjab is made by Surgeon-Major S. E. Maunsell, and an original contribution to the subject of the micro-organism of pneumonia is furnished by Mr. George M. Giles.

Taken altogether, the material given in this volume of the "Investigation Record" marks a decided advance in our knowledge of pneumonia, and future clinical writers or lecturers must levy tribute upon its pages.

We present some of the main facts of the report, furnished by the Committee and its individual members.

It is evident that there is an inclination to adopt the conclusion that acute lobar pneumonia is not the simple and single entity which it was once believed to be. Thus Dr. Sturges refers to the various forms of epidemic and contagious pneumonia under three heads, viz.:

1. Epidemic pneumonia, occurring in districts or houses after the manner of epidemic catarrh.

2. Pythogenic pneumonia, occasioned by sewer gas, fecal accumulation, and over-crowding.

3. Infectious pneumonia, imported into a house or district, and spreading from person to person. Dr. Sturges gives a brief review of the cases which have been reported in Great Britain, favoring the view that pneumonia appears under the forms above enumerated. These cases alone are not numerous enough to be of any great value, nor is it pretended that they form more than a link in the chain of evidence. Dr. Coupland reviews the foreign literature covering this same subject, and furnishes a great deal that is more positive. In the same line with these papers are the reports of epidemic pneumonia in the Punjab, and the article by Dr. Giles on the micro-organisms of pneumonia. This latter gentleman has made microscopical examinations and inoculation experiments, which, while not perfectly in harmony with those of Friedlander, do on the whole, he believes, corroborate that observer.

The evidence as to the infectious, and occasionally contagious character of pneumonia, furnished by the returns, supports, though only in a measure, the views discussed by the individual contributors. Out of the 1,065 cases, five observers only speak of epidemics of pneumonia attributable to atmospheric or meteorological conditions similar in character to influenza epidemics. Only three observers speak of "pathogenic cases." Nine independent observers express the opinion that pneumonia is, under certain circumstances, capable of transference from one person to another. Yet these gentlemen make the reservation that, possibly, in their cases it was only a similarity of conditions which caused the apparently contagious attacks. Despite this, as it appears to us, somewhat meagre evidence, the Committee feel warranted in believing that the infectious character of pneumonia in some cases is established, and that it, in very rare instances, is contagious. We reach the conclusion, from a survey of the whole evidence here furnished, that pneumonia may be, and generally is, simply a local inflammation; that in other cases it is a true infectious disease, a pneumonic fever; and that, finally, in rare cases this infectious fever is transmissible from person to person. It is shown further that the local disease, pneumonia, may be primarily excited by exposure to cold, etc.; or it may develop secondarily in the course of infectious fevers, or as the result of some poison or other depressing condition acting upon the vascular or nervous system.

Such are the more striking points suggested in the Investigation Record. But in addition a good many other things were brought out by the analysis of the returns. Thus it was found that pneumonia frequently attacks more than one member of a household at the same time; that when unusually prevalent the mortality is exceptionally low; and that defective house drainage and sewer-gas poisoning may both cause and favor the spread of the disease. It was also shown that alcoholic excess not

only favors the development of pneumonia, but may actually directly cause it; and that fatigue and mental depression rank next to alcohol in making the prognosis unfavorable.

The total mortality among the 1,065 cases was 192, or 1 in 5½. Subtracting from these the 105 alcoholic cases, the 14 cases produced by mental and physical depression, and the 22 infectious cases, and the mortality among the remainder was 108, or 1 in 8.

About one patient out of every ten had suffered from previous attacks of pneumonia, and it seems to the Committee safe to conclude that one attack predisposes to another. The mortality from second attacks is not greater than from first, but the same cannot be said of third attacks.

As regards heredity, there is no evidence that the disease runs in families, or that any other form of lung diseases is met with in excess in the families of those who have suffered from pneumonia.

In double pneumonia the disease runs a longer course, and is more liable to have a gradual termination.

Apex pneumonias were found to be as favorable in duration and mortality as other forms; when occurring in phthisical families they show no tendency to degenerate into phthisis, and phthisical families show no tendency to have apex pneumonias. These conclusions run somewhat counter to the received views on this point.

In another respect, also, the returns are at variance with the usual views, and that is as to the mode of termination of the attacks. Sudden remission is not the rule in pneumonia, and the only law which obtains in this regard is that, when the pneumonic pyrexia has lasted over eight days, its sudden subsidence is improbable. We are inclined to think that many physicians, in recalling their past experiences, will not be surprised at this conclusion of the returns.

As regards treatment, one cannot but feel some disappointment at the indefiniteness and valuelessness of the data given.

At the most we only learn what are the most popular measures among British physicians, without in the least being able to say which are the most effective, or whether any of them do any good. As regards local treatment, among 1,037 there were 287 who used poultices to the chest; 117, counter-irritants; 18, leeches; 2, wet-cupping; 9, cold sponging; 4, wet-pack; 3, warm baths, and 2 vapor baths.

As to internal or general treatment, 134 report having used the "expectant" plan—a rather small percentage for so excellent a method. Ninety-four used the "supporting" and roborant measures, carbonate of ammonia being one of the drugs most relied upon. Indeed, carbonate of ammonia was used by 250, and appears to be more uniformly given by British physicians than any other single remedy, excluding alcohol. In 94 cases antimonials were prescribed. Various expectorants were used in 214 cases, opium in 60, and bromides in 14 cases. Antipyretic drugs are rather in favor. Quinine was found in 143 returns, aconite in 125, digitalis in 65, salicylic acid in 41, veratria in 4. Ergot was given in 9 cases, belladonna in 3, phosphorus in 2, pilocarpin in 1, and colchicum in 1.

Alcohol was used in 424 cases, while in 104 it is expressly stated that no stimulants were used.

It must be confessed that an examination of the returns of treatment leaves one with a poor opinion of the value of British skill in treating pneumonia. Either they are much misrepresented, or the professional practice is to a large extent hap-hazard, and dependent on the peculiar education or bias of the practitioner. It is certainly strange that at this day it is found necessary to use from twenty-five to thirty drugs in pneumonia, besides "antiphlogistic" or "antipyretic" measures.

THE NEW LOCAL ANÆSTHETIC.

When we have heard and seen what the local application of cocaine hydrochlorate has done in abolishing pain, we are in danger of over-reaching the bounds of reasonable enthusiasm regarding its merits as an anæsthetic. Such of the ophthalmologists as have tried the salt cannot speak too highly of its wonderful power. Since the letter of Dr. Noyes appeared in our last issue, the ophthalmic surgeons have been vieing with each other to put the new anæsthetic to the severest test. As to what can actually be accomplished through its agency by the mere instillation of a few drops upon the most sensitive conjunctiva, is perhaps best appreciated by the perusal of the cases reported in the present issue by Drs. Agnew, Moore, and Minor.

So far as used it has been a great success, and there is possibly a future for its more extended application, not only in ophthalmic operations, but in general surgery. But this can only be determined by actual experience. The test for its still wider range of usefulness is yet to be made in ophthalmic practice. If its power to control pain in the operation of iridectomy can be established, the importance of the discovery of this anæsthetic will, in eye surgery at least, rank second only to that of ether itself. On general principles, it is fair to assume that, by increasing the strength of the salt and allowing more time for the manifestation of its effects, operations of the class mentioned may be performed without pain to the patient. At least it appears to us that a fair trial is warrantable on the rational presumptions offered.

It is not reasonable to suppose that, even from the present aspect of the question, we shall stop here. It is quite certain that in those numerous cases in which local anæsthesia is necessary for minor operations in surgery, gynecology, laryngology, otology, and even dentistry, this anæsthetic will be tested. Especially would it seem to be indicated in those parts of the body which are covered by mucous membranes and plentifully supplied with sensitive nerves.

As yet we know little or nothing of its possibly poisonous effects in large doses, and it is to be hoped that no rashness in experimentation will demonstrate them. With this introduction, cocaine takes its place in the line of new remedies, and awaits the verdict of an impartial trial.

THE ORIGIN OF YELLOW FEVER.

The unique, mysterious, and at the same time deadly, character of yellow fever, by which it is separated so markedly from all other fevers, has led to the most zealous investigations of its pathology. Hardly any disease has

called forth so many robustly defended and statistically fortified theories; in fact, yellow fever seems, like spiritualism, to have a tendency to unsettle the mind of the inquirer and turn him into a fanatic over his own special pathogenesis. Yellow fever, unlike other infectious fevers, lives only in certain regions where salt water, vegetable and animal decay, and tropical warmth exist; even these do not furnish all the elements for its sustenance. It exists only in the sea-ports of the tropical Atlantic and Western Mediterranean, from which places it stalks forth in the summer to attack other regions. Since 1647 outbreaks of the disease have occurred, and it has been a terror to all ships trading in the West Indies and Gulf of Mexico. In many of these West Indian ports it has become practically endemic.

Some modern sanitarians have been disposed to treat the subject of the origin of this disease lightly, and to deny the possibility or need of ever knowing how yellow fever came into being. Dr. Chaille, of New Orleans, once compared this inquiry to that of "the origin of a cat," which after all is a very respectable and not entirely hopeless object of research. Most of our more recent writers of text-books evade the question of pathogenesis altogether, or give the vaguest information about it.

If it were entirely accepted now that yellow fever does not rise *de novo*, the question of its origin would indeed have little more than an historical or scientific interest. Thus those who, like Dr. Hargis and Mr. Gamgee in late years, have claimed that the disease arises in ships, cannot deny that the conditions for producing it arise anew each year. The general tendency of opinion, however, is certainly against the ship origin or the *de novo* origin of yellow fever.

In the October number of the *North American Review*, Dr. C. Creighton gives a very interesting and vigorous exposition of another hypothesis, first put forward by Audouard. This hypothesis is that yellow fever arose from the slave-ships which carried on their traffic in the last and the early part of the present century.

The arguments put forth are briefly these: Yellow fever is a disease of tropical sea-ports, but limited only to a few of them. These ports of yellow fever are mostly the old ports of debarkation in the slave trade, its first appearance being at Bridgetown, twenty years after slaves began to be imported. The exacerbations of the fever have, as a rule, corresponded with the most lawless periods of the traffic.

These slave-ships contained hundreds of negroes crowded together in the hold, where they lived in filth and developed unspeakable stenches from the accumulated excretions of their bodies. Cases are related, showing that under these conditions a form of diarrhœa broke out among the negroes, and that then yellow fever broke out among the crew, the negro himself being rarely affected. These slavers having arrived at port with their crew and cargo, discharged the latter and then cleaned out their ships, pumping the bilge-water and the accumulated filth of the voyage into the harbor. This being done for years in the almost tideless harbor of Havana, for example, the bed and shores have become infected with the specific germs, by which the disease is kept endemic and the port a distributing centre. This fatal mud, says Dr. Creighton, has long been washed away from the Delaware, from Charleston, and all other Atlantic ports. It would have disappeared from the Gulf ports but for the sluggishness of the waters. It may long stay in the West Indies as a kind of Nemesis for the horrors and cruelties of the "middle passage."

Audouard's theory, thus revived and eloquently defended by Dr. Creighton, contains much that is plausible.

Certain it is that if the filth, heat, and effluvia generated by human crowding could ever originate a new disease, a specific fever, the old slavers furnished the conditions.

The objections which will be raised are that the theory is too narrow. A single case well substantiated might upset it. The old slavers might well have originated yellow fever, but can we say that they were its only source?

THE COMMA-BACILLUS OF CHOLERA NOSTRAS.

At the meeting of German Naturalists and Physicians at Magdeburg, September 18 to 23, Professor Finkler, of Bonn, made a most important communication regarding the cholera bacillus. He announced that as the result of a series of experiments made by Professor Prior and himself, they had discovered a comma-bacillus in the stools of cholera nostras. They had cultivated this organism on gelatine and other substances, and had studied carefully its life-history. Microscopically it was identical, or nearly so, with Koch's comma-bacillus. In its growth, however, it finally develops spores, and after a time only micrococci are to be seen in place of the bacilli. It is claimed that these spores are the "resting-state" of the bacillus. Cholera stools two weeks old were taken. No bacilli, but only micrococci and other forms were found in them. Cultivations were made, and the comma-bacilli developed.

Specimens of the bacillus of cholera-nostras have been taken to Berlin and shown to Dr. Koch, who acknowledges the similarity of their appearance to the bacilli of Asiatic cholera.

Inoculations of the cultivated bacilli, made by Prior and Finkler in dogs and rabbits, have as yet given no decided results.

Prior is positive that the disease from which he obtained the organisms was cholera nostras.

The significance of the discovery is certainly very great, but we abstain from comment until further particulars reach us.

Dr. Samuel Morgan Valentine, born in New York City, and a resident thereof, died in Lucerne, Switzerland, August 7, 1884, after a short illness, resulting from disease of the heart. He was graduated from the College of Physicians and Surgeons in 1838, and after a thorough course of study in Europe for two years, returned to this country, and engaged actively in practice, till other matters requiring his attention he was obliged to relinquish his professional duties. Though long living a retired life, Dr. Valentine always retained his interest in medicine, was well known to the prominent physicians of the city, and was respected for his sound judgment and his many kindly qualities of character. At the time of his death he was still a member of the New York County Medical Society.

News of the Week.

The Mississippi Valley Medical Association, at its annual meeting, September 23–25th, at Springfield, Ill., elected the following officers: *President*—Dr. F. W. Beard, of Indiana. *Vice-Presidents*—Dr. A. B. Miller, of Missouri; Dr. J. A. Sutcliffe, of Indiana; Dr. E. H. Luckett, of Kentucky. *Secretary*—Dr. G. W. Burton, of Indiana. *Assistant Secretary*—Dr. H. J. B. Wright, of Illinois. *Treasurer*—Dr. A. M. Owen, of Indiana. It was decided to hold the next meeting at Evansville, Ind., on the second Tuesday of June, to continue three days.

The Successor to the Late Professor Cohnheim.—The candidates for the vacant position of Professor of Pathological Anatomy at Leipsic are Rindfleisch, Klebs, Ziegler, and Weigert. Dr. Koch's name has also been mentioned, but we learn by cable that he has declined the proffered chair.

Dr. Alexander H. Stevens.—Dr. A. C. Post writes: "Allow me to correct an error in The Record of October 4th. Alexander H. Stephens was a distinguished politician of Georgia. Alexander H. Stevens was the eminent New York surgeon."

Cremation of Paupers.—It is proposed as a measure of economy to burn the dead paupers of Brooklyn, instead of, as is at present the practice, burying them in two-dollar soap-boxes. However admirable this scheme might be, practical men will see the futility of trying to carry it out, since it would prevent the Brooklyn politicians from making their usual percentage on each coffin.

A Field for Ophthalmology.—Professor Mosely has discovered an animal—a mollusc—which has 11,000 eyes. "If only men and women were thus poly-ocularly endowed," sighs the young ophthalmologist.

A Case of Scarlet Fever in a Canary is reported by Dr. Frank Ogston, of Aberdeen, in the *British Medical Journal*. The bird was in a room where two children lay sick with the same disease. The animal's skin was bright scarlet, its throat apparently sore, and it finally died.

"Vienna" Surgery.—This is the term popularly applied in this city to "bold" surgery, *i.e.*, such as is done for the benefit of the surgeon rather than the patient. We are glad to say that there is not much of it just now.

A Proposed Electro-therapeutical Association.—It is proposed to hold a convention of physicians at Waco, Texas, on October 30th, for the purpose of forming an Electro-therapeutical Association.

Berlin News.—The Berlin correspondent of the *Allgemeiner Wiener Medizinische Zeitung* writes that Prince Bismarck recently asserted in the Reichstag that medicine had made no progress in two thousand years! The same correspondent writes that the week in Berlin has been a very quiet one; Professor Schweninger had received no new decoration.

A Medical President.—Dr. Don Rafael Zaldivar, President of the Republic of San Salvador, is said to be a very accomplished physician. He has just been chosen for a third term, and is now travelling in Europe.

The Harveian Oration was delivered this year on October 18th, by Dr. Russell Reynolds.

The Académie de Médecine, of Paris, held a meeting on September 16th. M. Hervieux made a report upon revaccination. He gave the experiences of Surgeon-Major Burlureau, who in 210 cases had obtained successful vaccinations in 61.43 per cent. M. Hervieux, among 312 cases, had had 66.33 per cent. of success. The Academy then passed to the subject of the treatment of cholera.

Ten Thousand Dollars for Prizes.—The sum of 40,000 francs has been left to the Faculté de Médecine, Paris, to found a biennial prize in hygiene. The sum of 10,000 francs has been left for a prize in histology.

The Change of View.—"Nearly forty years ago," says Dr. R. W. Matthewson in the Proceedings of the Connecticut Medical Society, "I had the honor to report the name of Fordyce Barker, a member of this Society, for Dissertator. His subject was 'Local Treatment of Uterine Diseases by the Speculum.' This was considered such an innovation on old customs that many of his friends feared it would injure his professional character. When Dr. Bedford, of New York, first opened his clinics, his exposure of females was severely denounced by some of the medical journals."

Midwives in Detroit.—Says the *Detroit Lancet*: "Since the training school for nurses has opened with a liberal endowment, at Harper Hospital, in Detroit, the nurses, including some of the best of the midwives, have organized themselves into a society, by which they propose to emulate the attainments of the graduates of the nursing school. They have procured regular instruction from members of the medical profession proficient in the art and science of midwifery. They are said to be quite particular as to those whom they admit to membership."

The Autopsy upon Cohnheim.—There is a certain grim satire in the careful accounts of the post-mortem appearances of the great pathologist Cohnheim. Dr. Huber, who made the autopsy, reports: Contracted gouty kidneys, the right being the smaller and both containing calculi, arterio-sclerosis; extreme excentric hypertrophy of both ventricles; brown induration of both lungs, on the left side hydrothorax, on the right pleuritis; infarction necrosis in the left kidney.

The Minnesota College Hospital has had its mortgage foreclosed and it is financially defunct. The city of Minneapolis is not large enough to support the institution. The college connected with it, however, continues its work.

Another Free Medical College.—The Medical Department of the University of Colorado, at Boulder, has begun its sessions. Tuition is free, and $6,200 have been appropriated to build a hospital.

Another Tri-State Society.—A movement was set on foot at the recent meeting of the Medical Society of Virginia to organize a Tri-State Medical Society, representing the States of Virginia, West Virginia, and North Carolina.

The Chicago Medical Society announces that there is now a collection of twelve hundred standard medical works in the Public Library.

A Slander on the Texans.—Our esteemed but fiery contemporary, *The Texas Courier-Record*, devotes two or more pages of editorial incandescence to the wilting and extinguishment of a Philadelphia professor who asserted that it was "a common practice in Texas for the mothers to chew the food for the children, regurgitate and spit it out, and then feed it to them." The editor of the *Courier-Record* affirms this to be a disgusting and infamous slander. He further expresses a deep desire to get hold of the author of the slander and apply a coat of tar and feathers in a manner that would strain the most liberal interpretation that could be put upon the Code of Ethics. The real facts seem to be that there is a practice existing in several Southern States on the part of mothers of softening a bit of cracker or biscuit in the mouth, then giving it to the baby. The starch in the cracker is turned to sugar by the saliva and the infant's food partly digested. This procedure is, therefore, claimed to be physiological and rational.

COCAINE HYDROCHLORATE THE NEW LOCAL ANÆSTHETIC.

[The reports of the following cases, illustrating the surprising effects of cocaine hydrochlorate as a local anæsthetic in ophthalmic operations, come to us just as we go to press. The results are certainly very encouraging, and will doubtless command the attention they deserve. —Ed.]

By Professor C. R. AGNEW, M.D.,

NEW YORK.

In your last issue is a letter from our distinguished colleague, Dr. H. D. Noyes, in which there is an allusion to the new local anæsthetic, hydrochlorate of cocaine, as recently discovered and applied in Germany. We have to-day (October 14, 1884) used the agent in our clinic at the College of Physicians and Surgeons, with most astonishing and satisfactory results. If its further use should prove to be equally satisfactory, we will be in possession of an agent for the prevention of suffering in ophthalmic operations of inestimable value.

It is difficult to avoid expressions of extreme enthusiasm in view of what we have to-day seen and in view of what we may rationally expect from the further applications of the agent. The following cases, however, will be of more value than any abstract disquisition.

Case I.—A. E——, aged five; a case of convergent squint. A two per cent. solution of the hydrochlorate of cocaine was dropped upon the surface of each eye three times at intervals during a period of fifteen minutes, without any more irritation of the eyes than would have been caused by drops of common water. At the end of twenty-five minutes he walked into the operating-theatre, laid down upon the operating-chair, and allowed the spring speculum to be inserted between his eyelids, the scleral conjunctiva to be seized with fixation forceps and cut with scissors, and the rectus internus of the left eye to be divided without complaining or showing any signs of suffering. When we had the internus tendon upon the strabismus hook, he said we were pulling something.

Case II.—L. H. B——, aged eleven; convergent squint. Solution applied as above, three times in fifteen minutes, at the end of which time he sat erect in a chair, resting his head upon the breast of an assistant, had the speculum inserted, scleral conjunctiva seized with fixation forceps, and the internal rectus divided in the usual manner, and when asked said the operation had given no pain.

Case III.—Joseph McC——, aged six; convergent squint. Solution applied as above. In the delays of the clinic somewhat more than half an hour elapsed between the last instillation of the agent and the attempt to operate The youngster seemed to be much frightened by the presence of the surgeon and students; would not submit to the proposed strabotomy, and ether had to be administered before it could be done. As his scleral conjunctiva was insensible to the contact of the fixation forceps fifteen minutes after the first instillation of the solution, it is a fair inference that the anæsthetic benumbing had passed away before he entered the operating-theatre. His nervous apprehension was so great that he would not have endured an operation even though there might have been no real pain inflicted.

Case IV.—James McG——, aged fifty-two, was sent to the clinic with the statement that he had a lacerated wound of his left eyeball involving the sclerotic. His dread of handling and of light was so great that we could get no view of the injured organ, as every attempt to inspect it was instantly followed by blepharo-spasm. A few drops of the solution were instilled, and in a few moments the patient walked into the operating-theatre with the injured eye open and so free from irritability as to make an examination of it before the students quite easy.

Case V.—J——, a physician, aged seventy-one, with double cataract, consulted us on October 15th. His eyes were extremely sensitive to touch. A drop of the two per cent. solution was dropped upon the scleral conjunctiva, and in two minutes and a half the patient permitted me to apply the end of a forefinger to the scleral conjunctiva without wincing.

The solution used in all these cases was a two per cent. one, made with distilled water and with Merk's crystals of the hydrochlorate of cocaine.

It is only by extensive gathering of the clinical facts in regard to this new agent that we can reach just conclusions as to its value, and it is important that all observers should give the profession the benefit of their experience The operations at the clinic alluded to above were done with the assistance of Dr. David Webster, Dr. W. Oliver Moore, Dr. Neil J. Hepburn, and Dr. W. A. Pierrepont, and in the presence of the class.

By WILLIAM OLIVER MOORE, M.D.,

PROFESSOR OF EYE AND EAR DISEASES, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

Cocaine has been known since 1855, and is the active principle of the leaves of the Erythroxylon coca, a South American plant, the leaves of which resemble very much those of the tea plant. Many of the natives during hard work use these leaves, chewing them with some alkaline substance, going without food the entire day, but taking their food at night. It has long been known as a powerful stimulant. Cocaine hydrochlorate is of more recent origin, and the anæsthetic effect of it when brushed or dropped upon mucous surfaces has been only known about a year, it having been used in Germany first by the laryngologists, to produce anæsthesia of the vocal cords and surrounding parts to facilitate manipulation. In this journal, page 417, in a letter from Dr. H. D. Noyes, of New York, an account is given of an experiment made with this drug before the Ophthalmological Congress at Heidelberg, where a solution of the cocaine hydrochlorate was dropped into the eye, the result being complete anæsthesia of the conjunctiva and cornea. Dr. Noyes is justly enthusiastic on the subject, and his letter caused me to obtain some of the drug for experimentation, the results being annexed.

A two per cent. aqueous solution of the cocaine hydrochlorate (Merk's) is procured and dropped into the eye, two drops being sufficient at first; the eye is then closed, and in five minutes two more are instilled; after five minutes more have elapsed, as a rule, anæsthesia is complete; if not, two more drops may be used. There is no pain attending the application.

The following experiments were made with very satisfactory results:

CASE I.—Chinaman, with keratitis. Two drops of a two per cent. solution of the cocaine hydrochlorate were dropped into the left eye, then closed; after five minutes two more drops were used; at the end of fifteen minutes from the first instillation I was able to grab the ocular conjunctiva with fixation forceps and move the eye in any direction without pain or any disagreeable sensation. The ulcer of the cornea was also touched and gently scraped without sensation. In the right eye, where none of the drug had been used, the patient made loud demonstrations of complaint on my attempt to use the fixation forceps, as in the first instance; in short, there was a marked difference in the eyes. The anæsthetic effect in the right eye had entirely disappeared in thirty-two minutes from the beginning of the experiment.

CASE II.—Man, aged thirty-seven, with double pterygium. In one eye, the left, I put in two drops of the solution, and after waiting five minutes introduced between the lids two drops more; after another interval of five minutes two more were used.

Five minutes after the last drops were used the operation was begun, the pterygium being excised by scissors, the conjunctiva being freely cut, and the cut surfaces brought together by three sutures. This usually painful operation was done with the utmost ease, and without any painful sensation, the patient being surprised at its completion.

In the other eye the cocaine was not used, and the pain and suffering of the patient was, as usual, when ether is not used. The effect was very marked, and really very surprising. The anæsthesia lasted twenty-five minutes.

CASE III.—Child, seven years old, having squint (strabismus convergens). Two drops of the solution were put into the squinting eye, and repeated as in the other cases till six drops in all had been used during the space of fifteen minutes; at the end of which time the conjunctiva was sufficiently quiet to allow of the tenotomy of the internal rectus muscle, the usual operation being performed, the spring speculum being used. The little boy made no complaint of pain, and simply said the speculum stretched the lids, but was painless. That it is unusual for a child of this age to allow an operation of this sort to be done without ether is at least a marvel, and to show that the patient, though young, had not "pure grit" the other eye (the one in which no cocaine had been used) was tried, and found to have the normal sensations.

I have tried it in other cases, yet this will suffice to bring it before the notice of the profession at once. Several of my confrères at the New York Eye and Ear Infirmary and elsewhere have used the same solution with good effect. Much more will be written on this subject, as it has a wide application, and we have yet to learn much of the properties of the alkaloid. The introducer of this new and truly magical preparation is a student in Vienna, Dr. Koller, *vide* Dr. Noyes' letter above referred to. I hope to say more of its practical value at another time.

BY JAMES L. MINOR, M.D.,

ASSISTANT SURGEON, NEW YORK EYE AND EAR INFIRMARY.

The last number of THE RECORD contained a short account of the proceedings of the Heidelberg Ophthalmological Congress, by Dr. H. D. Noyes. He speaks of the anæsthetic effects of the muriate of cocaine, and of its probable future in ophthalmology.

I have had an opportunity of using the drug on several cases, and with such beneficial effect, that I deem it important enough to lay before the readers of THE RECORD.

I used a two per cent. solution, kindly furnished me by Dr. Moore, after the manner described by Dr. Noyes—viz.: two drops were dropped into the conjunctival sac, and in ten minutes this was repeated, and the operation was performed ten minutes later.

CASE I.—A nervous boy, aged ten, upon whom I had operated for squint in the left eye three days before, presented himself on October 13th, with the conjunctival stitches still *in situ*. The solution of cocaine was instilled as above described. The cornea and the conjunctiva could be brushed with the end of the finger, without causing any uncomfortable sensation. The speculum was introduced, the stitches removed, the conjunctiva was grasped with fixation forceps, and the globe was pulled around by them. The child complained of no pain, and when asked after it was over if he had been hurt, he replied in the negative. The other eye retained its sensibility, and it could not be handled in the least.

CASE II.—A woman, aged fifty, upon whom I had performed a preliminary iridectomy a few weeks before, came for the extraction of the cataract on October 13th. She was nervous and very resentful of anything disagreeable or painful. When the iridectomy was performed, I attempted to do it without an anæsthetic, but found it utterly impossible to even retain the speculum between the lids, and resorted to ether. I decided to use the cocaine, and dropped it in the eye, on which she shrank back and closed the eye as tight as possible—resenting even this much handling of the eye—for the solution is non-irritating to the conjunctiva. The second application was made without difficulty, and I could rub my finger over the conjunctiva and cornea without causing discomfort. The speculum was introduced, the conjunctiva was grasped with fixation forceps, and the globe thus pulled in position. A large section of the cornea was made, and cystotomy and delivery of the lens were easily accomplished. The patient complained of no pain, and after the operation, and on the following day, declared that she had not been hurt in the least. She was even surprised when told that the operation had been performed. Immediately after the operation I tested the sensibility of the conjunctiva of the other eye, by lightly touching it with my finger. She shrank and closed the eye so quickly and violently that I feared the other eye would suffer from the violent contraction of the lids. The case has progressed, so far, as satisfactorily as could be desired.

Should cocaine in the hands of others meet with the same success that I have attained, it will mark an era in ophthalmology unsurpassed by any in modern times. Its use in other branches of medicine and surgery may be almost as important as in ophthalmology.

233 MADISON AVENUE, NEW YORK, October 15, 1884.

AMERICAN PUBLIC HEALTH ASSOCIATION.

Twelfth Annual Session, held at St. Louis, Mo., October 14, 15, 16, and 17, 1884.

(By Telegraph to THE MEDICAL RECORD.)

TUESDAY, OCTOBER 14TH—FIRST DAY.

THE session was called to order at 10 A.M. Dr. Albert C. Ghion, presiding. About one hundred and fifty members were present.

DR. J. SPIEGELHALTER, of the Local Committee, welcomed the members and announced the programme for the session.

An appointed committee recommended that members residing in the District of Columbia form into a body and secure incorporation of the Association. Adopted.

DR. J. ZERRIEN LINDSLEY, the Treasurer, reported a balance on hand with an admission of one hundred and twenty-five new members.

The Committee on Necrology reported, showing fourteen deaths.

The Conference of Charities and Corrections at present in session was invited to attend the meetings of the Association.

Dr. Charles W. Chancellor, of Maryland, read a paper on

TENEMENT REFORM,

dealing with the squalid dwellings of the poor, their unsanitary condition, and vice resulting therefrom.

Major Samuel I. Robinson, of the District of Columbia, read a paper on

THE HYGIENE OF THE HABITATIONS OF THE POOR,

abounding with practical suggestions regarding drainage, ventilation, etc.

Dr. William K. Newton, of New Jersey, read a paper on

THE SANITARY SURVEY OF A HOUSE,

urging that a sanitary history of all houses should be kept by municipalities.

The above papers were discussed by Dr. Hunt, of New Jersey; Erastus Brooks, of New York; Dr. Reade, of Ohio; Dr. Fee, of Kansas City; Dr. A. N. Bell, of New York; Dr. Raymond, of Brooklyn; Dr. Briggs, of St. Louis; Dr. Devron, of New Orleans; Dr. Bryce, of Toronto; Dr. Cook, of Nashville.

Mr. Brooks introduced the question of

LICENSING PLUMBERS,

instancing the good results following in New York.

Dr. George H. Rohé read a paper on

THE HYGIENE OF OCCUPATIONS,

giving statistics of average life expectation of the various trades and professions.

Dr. Adolph Alt, of Missouri, read a paper on

PROTECTIVE SPECTACLES FOR WORKINGMEN,

recommending that employers be made to force men in their employ to wear protective spectacles wherever there is danger from flying chips.

Prof. Charles O. Curtman, of St. Louis, read a paper on

HEATING AND VENTILATION.

The hot air principle is considered the best for public buildings.

Dr. W. Thornton Parker, of the U. S. Army, read a paper on

SANITARY MANAGEMENT OF RAILWAY CARS AND STATIONS.

He dealt with the danger of moving sick and convalescents in ordinary cars, and urged sanitary inspection of all trains and adoption of hospital cars.

The Association then adjourned.

Evening Session.

At 8 P.M. the hall was crowded with visitors, many ladies being present.

ADDRESSES OF WELCOME

were made by the Mayor of the city, Governor of the State, President of the State Board of Health, and others. A band of music enlivened the occasion.

The feature of the evening was the address by the President, Dr. A. L. Gihon, which was listened to closely, and frequently applauded.

October 15th—Second Day.

Papers were read on

SCHOOL HYGIENE

as follows: "Report of Committee on Compulsory Vaccination," by Dr. Geo. H. Homan, of St. Louis; "Hygiene of Eyesight of School Children," by Dr. Stephen O. Richey, of Washington, D. C.; "Sanitary Survey of the School-houses of Indiana," by Dr. E. S. Elder, of Indianapolis; "School Hygiene," by Dr. Felix Formento, of New Orleans, La.

THE FOOD QUESTION

was discussed under the following heads: "Cotton-Seed Oil as Food," by Prof. C. E. Munroe, of Annapolis, Md.; "Poisonous Cheese, Canned Beef, Sausage, etc.," by Prof. V. C. Vaughn, of Michigan; "Milk Supply of Large Cities," by Dr. Cheston Morris, of Philadelphia, Pa.

Afternoon Session.

On invitation, Dr. J. V. McCormack, of Kentucky, read a report adopted by the Conference of States Board of Health relating to

THE BEST MEANS OF PREVENTING THE APPEARANCE OF CHOLERA IN THIS COUNTRY.

The report of the Conference stated that there were three essential factors to the prevalence of cholera: 1, The importation of the disease by means of ships; 2, local unsanitary conditions; 3, persons sick with the disease, or things infected by such sick persons. In view of the threatened introduction of cholera into this country during the coming year, it was the sense of the committee that the Government should maintain a national health service, which should establish an effective system of quarantine by the appointment of medical officers at foreign infected ports; that emigrants shall be prevented from landing until the danger of the introduction of cholera has been ascertained. The inspection and quarantine service inaugurated by the National Board of Health met with the approval of the committee, which recommended that Congress be urged to appropriate $500,000 to be used for the purpose of stamping out the disease should it become epidemic.

The committee was of the opinion that State Sanitary Inspectors should be appointed to visit all towns and cities especially liable to the disease to consult with the local authorities as to the best methods of prevention. This work should be vigorously prosecuted before the disease reached the American shores. The report also recommended the isolation of victims of the disease, and the destruction of their clothing and the discharges from their bodies.

The Association unanimously endorsed the report of the States Board of Health Conference, and a motion was adopted that said report be printed and copies of it sent to the United States Cabinet officers, Members of Congress, and all State and local Boards of Health of this county and Canada.

A motion by Dr. Hibberd, of Indiana, to appoint a committee to report on antiseptics and germicides, was referred to the Executive Committee. The rest of the session was devoted to reports from the various States on the progress of sanitation during the past year.

THE PAPERS READ AT THE EVENING SESSION.

An audience of one hundred and fifty was present, including quite a number of ladies. Papers were read as follows: "The Food we Eat and the Adulterations to which we Submit," by Hon. Erastus Brooks, of New York; "The Hygiene of Sailors engaged in the Coasting Trade," by Dr. Walter Wyman, U. S. Marine Hospital Service; "Cremation as a Safeguard against Epidemics," by Rev. John D. Bengles, Chaplain U. S. Navy; "The Ultimate Sanitation by Fire," by Hon. J. M. Keating, of Memphis, Tenn. These papers were discussed and the Society adjourned at 11 P.M.

HOW THE MEETING IS ATTENDED.

The attendance of members is quite large, but little local interest is manifested in the proceedings. Toward the end of the afternoon session there were not more than twenty members left in the hall, and these would have been left in the dark if a non-member had not taken upon himself the duty neglected by the local Committee of Arrangements. The papers, as a rule, are carefully prepared and of practical value, but the discussions are spiritless. The usual social entertainments and courtesies are not neglected.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, September 24, 1884.

GEORGE F. SHRADY, M.D., PRESIDENT, IN THE CHAIR.

SARCOMA OF THE MEDIASTINUM AND LUNG.

DR. VAN GIESON presented a specimen accompanied by the following history, and for both he was indebted to Dr. W. F. French, House Physician at St. Catharine's Hospital, Brooklyn, N. Y.: D. N——, forty-one years of age, married, German, was admitted September 11, 1884. On examination the chest revealed the following physical signs: over the upper lobe of the right lung there was entire absence of respiratory movement, absence of vocal fremitus, complete dulness, and absence of respiratory sounds, unaltered by change of position. The patient was emaciated, and had œdema of the left upper eyelid and orbital region. There was no œdema of the extremities. There was tympanites, dyspnœa, cough without expectoration, nausea without vomiting. The left side of the thorax was normal. There was no family history of cancer. There were no symptoms referable to the uterus. The patient died September 16, 1884. The autopsy was made on the 17th. Body emaciated, and rigor mortis only slight. Head and uterus not examined. The heart was normal; the pericardium contained eight onnces of clear serum. Lungs: Outside of the pericardium, in the anterior mediastinum, there was a mass of infiltrated glands, about the size of the fist. In the anterior portion of the upper lobe of the right lung was a dense infiltration in the form of filbert-shaped nodules of a white color, and bound together with a fibrous stroma. The growth was regarded as cancerous. The remaining portion of the right lung, with the exception of a few adhesions at the base, was apparently healthy. The left lung was apparently normal. The bronchial glands were involved. The right bronchus was constricted to the size of a No. 8 English urethral sound. The spleen and kidneys were normal, and the liver was slightly fatty.

Dr. Van Gieson remarked that the fact that the uterus was not examined might give rise to doubt as to whether or not the patient might not have had cancer of that organ; there was nothing in the clinical history, however, which turned the attention of the house staff in that direction.

Microscopical examination, so far as it had been made, determined the growth in the thorax to be sarcoma rather than cancer.

The absence of vocal fremitus was a feature of interest in the clinical history, and it could be accounted for by the constriction of the bronchus. In another case seen with him by Dr. Janeway in consultation, the same condition of absence of vocal fremitus was noticed, and that fact aided somewhat in the diagnosis.

THE PRESIDENT remarked that the new growth probably began in the mediastinum.

DR. VAN GIESON said that was the opinion of the gentlemen who made the microscopical examination.

THE PRESIDENT asked if the bones were examined.

DR. VAN GIESON thought they were not. There was no evidence, however, of disease of either the sternum or the ribs.

THE PRESIDENT regarded sarcoma of either the lungs or the mediastinum as quite rare, independent of the previous existence of the disease in some other part of the body, especially the bones.

DR. VAN GIESON remarked that in a somewhat similar case œdema of the eye without protrusion was noticeable, and there was no evidence of new growth in the cellular tissue of the orbit. In that case the œdema was accounted for on the ground of pressure upon the blood-vessels of the neck.

ACUTE PHAGEDENIC PUSTULAR SYPHILIDE.

DR. JOHN A. WYETH presented a patient with the following history: Samuel J——, bookkeeper, German, thirty-five years of age. Was admitted to Mt. Sinai Hospital July 11, 1884. Previous to the present attack he had had illicit intercourse frequently, had had gonorrhœa many times, the last attack being nine months ago. He had had no urinary trouble at any time. Five weeks and a half ago the patient had sexual intercourse with a prostitute, and about one week later he saw a small blister one-fourth of an inch in diameter at the base of his penis. This blister remained of apparently the same size for the next ten days, when he again had sexual intercourse, and a few days after the last exposure, the sore upon the base of the penis began to enlarge and became painful, and it had been steadily extending up to the time of admission to the hospital. The sore has been painful, and during the week prior to admission prevented sleep. He had had a bubo on the right side, that had been painted with iodine which reduced its size somewhat, and rendered it less painful than it was at first. The sore upon the penis had been treated with iodoform and charcoal poultices.

The patient's general health has been good, no cough, feet never swollen, no rheumatism. On admission, there was found a large non-suppurating bubo in the right groin, and a sore with indurated edges at the base of the penis on the right side. The sore was triangular in shape with the apex extending up the penis, one angle at the base running into the scrotum, and the other into the groin. The sore measured about one inch on each side, and was deeply excavated, measuring more than an inch in depth, and it had a sloughy base.

A papular and pustular eruption was scattered thickly over the face, trunk, and extremities. The inguinal, epitrochlear, and cervical glands were enlarged. There had been a small ulceration upon the dorsum of the tongue, which lasted about two days.

The patient's general condition was good; his bowels were regular; there was no urinary trouble; his tongue was coated; his mouth dark red; and his temperature 102.2° F.

July 15th.—The cavity of the sore was swabbed out with deliquesced chloride of zinc, and packed with iodoform gauze.

July 23d.—There was still some phagedena at the angles of the sore, which was touched with chloride of zinc 1 to 4, and dressed with iodoform.

July 31st.—The eruption had gradually increased in size, and now many of the pustules measure three-fourths of an inch in diameter, and are covered with scabs raised half an inch in circumference, domed and black, and surrounded by a reddish areola.

August 7th.—Ulcer now level with the surface and looks well. The patient takes protiodide of mercury gr. j. t.i.d.

August 8th.—Ordered inunctions, ung. hydrarg., 3 ss. every night.

September 4th.—Scabs have nearly all fallen, leaving ulcers which are rapidly healing.

Dr. Wyeth remarked that the case had shown phagedena to a degree he had not seen before with an acute syphilide. There was no evidence of tertiary lesion. He regarded the case as one of acute phagedenic pustular syphilide, and maintained that it illustrated the statement of Bumstead and Taylor that a pustular syphilitic eruption is apt to follow a phagedenic syphilitic ulcer on the penis, and the violence is frequently proportionate to the violence of the initial lesion.

A point of interest in the treatment was the fact that very large doses protiodide of mercury were given daily for three or four weeks before the sores began to heal, and no unpleasant constitutional effects belonging to the drug were produced.

DR. VAN GIESON asked if self-inoculation was ruled out entirely.

Dr. Wyeth replied that it was not absolutely, although he was unable from the clinical history to ascertain its existence.

Dr. Van Gieson had seen a similar case, in which there was a mixed sore, because there was a history of two intercourses. He regarded it as extremely difficult to draw the border line in cases of that kind.

Dr. Wyeth had recognized the difficulties attending a complete diagnosis, and had also been convinced, the more he studied the disease, of the great variety of the manifestations of syphilis.

Dr. Levi referred to what Mr. Jonathan Hutchinson had called syphilitic lupus, and had seen three cases, of which he had been reminded by the case presented by Dr. Wyeth. He further remarked that in Vienna syphilis was diagnosticated by the disease attacking the root of the nose, while lupus attacks the apex of the nose.

Dr. Wyeth remarked that in his case the disease attacked not only the nose at the apex, but other portions of the body, and was seen upon the forehead, etc. He regarded the lesion upon the apex of the nose as due to strangulation of the vessels.

Dr. Levi remarked that he did not doubt the correctness of the diagnosis in Dr. Wyeth's case, and merely mentioned the point made by Mr. Hutchinson that syphilis was one of the causes of lupus, of which he had seen cases which had a striking resemblance to the one presented.

Dr. Van Gieson asked if, when the initial lesion was pure chancre, extensive destruction of tissues at the seat of the lesion was to be expected in ordinary cases?

Dr. Wyeth said no: that true chancre was not apt to be ulcerative, but there are forms which are chancroid in type.

Dr. Van Gieson referred to one case of syphilis under his care, which resisted all forms of treatment. The case was also treated by Dr. Bumstead, but without effect, and he (Dr. Bumstead) regarded it as one of the cases in which the poisoning is so profound that it could not be reached by ordinary remedies. The beginning of the case was very much like that of the one presented by Dr. Wyeth. The initial lesion was upon one labium, which sloughed away entirely and very rapidly, and before the disease could be arrested the opposite labium was involved and also completely destroyed. The secondary symptoms were of the most obstinate character, were followed by iritis and the later eruptions, despite the most active mercurial treatment. The rodent variety, therefore, might be seen early in the history of a case.

Dr. Wyeth thought that such cases were not so rare as they might appear to be. Some cases of syphilis resist all forms of treatment and go on to a fatal termination without abatement of the disease. In other cases the patients live for years without the recurrence of symptoms, after having been under treatment. He regarded syphilis as a curable disease and not a difficult disease to cure. At all events he preferred to take his risks with syphilis rather than typhoid fever or pneumonia. He also believed that thousands of cases of syphilis had recovered without medicine which produced any direct effect upon the poison of the disease.

Dr. Van Gieson remarked that the point to which he wished to make special reference was the early appearance of the phagedena. He had had a patient under observation who was treated for syphilis *ten* years ago, and it was supposed that he was cured, but at present he was suffering from paralysis of the abducens believed to be of syphilitic origin, *without having contracted the disease a second time.*

Dr. Seguin remarked that nerve phenomena of a syphilitic character might develop as long as twenty-five years after the disappearance of all symptoms of the first attack, and this also in cases in which the primary syphilitic attack was mild.

The President referred to 9 cases in which syphilitic lesions developed twenty years after the primary attack, and the patients had been reasonably well treated at first.

Dr. Wyeth remarked that in many cases syphilis remained dormant in the system for twenty or thirty years, and then tertiary symptoms developed,

Dr. Levi remarked that the fact that the initial lesion in Dr. Wyeth's case was pustular made him believe that the general system of the patient was affected by something besides syphilis. With regard to treatment, whenever mercury had failed to control the disease, it had frequently occurred that to stop all specific remedies and resort to hygienic measures with cod-liver oil and iron was the very best method of treatment which could be adopted.

The President had often adopted this plan, and had even begun the use of cod-liver oil, iron, etc., before administering mercurials.

The Society then went into executive session.

Correspondence.

OUR PARIS LETTER.

(From our Own Correspondent.)

THE PROPOSED AMBULANCE SYSTEM IN PARIS AND DR. NACHTEL—THE REPORT OF THE CHOLERA EPIDEMIC.

Paris, September 26, 1884.

The readers of The Record may recollect that so far back as the year 1880 Dr. Nachtel submitted a proposal to the Academy of Medicine and to the Municipal Council of Paris for the introduction of ambulance carriages to meet the requirements of this populous city in case of street accidents, as at present nothing of the kind exists. He even offered his services gratuitously to assist in the organization of a system similar to what has been so long in operation in New York, and which has rendered such signal service. Dr. Nachtel's plans were highly approved of and accepted in principle, but, however incredible it may seem, nothing has as yet been decided upon. There has been no lack of perseverance on the part of Dr. Nachtel, for he has been unremitting in his endeavors, and he has not left a stone unturned to have his scheme carried out. He has paid personal visits to officials whom he thought in a position to help him in the matter, from the Prefect of Police to the President of the Republic, by whom he was received with the usual French politeness, but the affair is not a whit more advanced than it was four years ago. Finding little hope from official quarters, Dr. Nachtel has, from time to time, appealed to the public through the medical and lay press, but without any better result. He has now published a pamphlet in which he has taken the pains to recall the different phases through which the subject has passed since 1880, and to reproduce the various documents he has officially submitted to the Academy of Medicine, to the Council of Hygiene, and to the Municipal Council of Paris, and once more makes an appeal to all whom it may concern (and surely it concerns everybody residing in this city or only passing through) to have Dr. Nachtel's scheme realized without further delay, as street accidents are as rife as ever and the existing arrangements are quite inadequate to meet them. The following statistical report just published by the Prefect of Police will show the necessity for having ambulance carriages at the disposal of the population. The report relates to accidents in Paris and in the suburbs during the year 1883. The total number of accidents during the year was 759. Of this number there were 208 cases of wounds of the head and 192 cases of drowning; there were 212 cases of wounds produced by various causes, 59 cases of illness of various kinds, and 31 cases of epilepsy; 182 persons received medical aid in the eight pavilions established along the banks of the Seine and of the canals in Paris for succoring the drowned.

To give strength to his cause, Dr. Nachtel has even

secured the support of Victor Hugo, whose voice he thought, from his high standing in the favor of the nation, would attract some notice. The idea was as far-fetched as it was a happy one, as Victor Hugo is not only a great poet but he is also a great philanthrophist, and in the latter capacity he expressed himself as follows: "New York has commenced, Paris will continue that which you propose, and which is suggested by reason and by evidence. The success of the scheme will confirm your affirmations; it is clear, it is definite, it is humane. I approve of it and congratulate you." The above is a translation of Victor Hugo's autograph letter to Dr. Nachtel, which has been reproduced in the pamphlet above referred to, but I am afraid the French will pay no more heed to it than they would to any of the great poet's poetical effusions.

The French are a peculiar people, they are quick in some things and deplorably slow in others. And one of the things they are slow in is the adoption of any innovation coming from a foreigner. Moreover, they are so tied down by red-tapeism that, even in the management of their internal affairs, when a proposition is made by one of their own for the public good, the course it has to go through before it is sanctioned or pronounced upon is so interminable and attended with such vexatious processes that in many cases the proposition is either forgotten or hopelessly abandoned. In this assertion I am supported by an editorial in a recent number of the *Progrès Médical*, in which the writer, with reference to this very question of ambulance carriages as proposed by Dr. Nachtel, states: "Unfortunately everything is done very slowly in France, and practical questions are long since resolved by our friends, the Anglo-Saxons, before they are even broached by us. In spite of our superficial love for novelty, we are, at the bottom, great followers of routine, and we bear with astonishing patience all the defects of an administration for which Europe has never envied us." I have translated the original paragraph as literally as possible, in order that I may not be accused of undue exaggeration, although it is hardly necessary to offer any apology, as what is stated above is a proverbial fact. I consider it highly discreditable to the country, the inhabitants of which assume to be in the van of progress and civilization, to be so exclusive and so adverse to foreign intervention, even when it affects their nearest interests, for while the scheme above referred to is long since in operation in London and in many other manufacturing towns in England and Scotland, Paris is still without its ambulance service.

I may here recall another instance of French repugnance to foreign innovations. It so happens that Dr. Nachtel is here again the instigator. I refer to the necessity of adopting some system to prevent people being run over by cabs and other vehicles moving about the city of Paris. More than a year ago the subject was brought to the notice of the Prefect of Police and a plan was submitted to that functionary for carrying out this very desirable and philanthropic object, but nothing has been heard of it since. The consequence is people are still being run over and the victims are left to the tender mercies of the public, as no particular arrangements are made for attending to them. It is true that refuges in the streets have been multiplied, but they are few and far between and are often not to be found where they are most required. The plan suggested was that adopted in London and New York, but I have it on good authority that the Paris policemen have received no particular orders to interfere with the vehicles going to and fro, or to render assistance to pedestrians in the streets unless they were moved to do so by their own sense of courtesy or humanity.

Dr. Proust, Inspector-General of the Sanitary Services in France, has just sent in his official report to the Minister of Commerce on the state of the cholera epidemic. The report was published in the *Journal Officiel* in which he states that the epidemic is evidently on the decline, thanks to the energetic measures that have been taken to ensure salubrity in the dwellings, as well as in the streets. The progress of the present epidemic in France and Italy demonstrates once more the futility and even the danger of "cordons sanitaires" and the necessity for the rigorous application of hygienic measures.

OUR LONDON LETTER.

(From our Special Correspondent.)

BUYING PRACTICES — MEDICAL AGENTS — BACILLI AND THEIR DISCOVERIES—THE ADVANCE IN ANTISEPTICS—THE ANTI-VACCINATION CRAZE.

LONDON, September 29, 1884.

THE holiday season is now fairly over, and so is the fine weather. Most practitioners are now reassuming harness for the winter. Among general practitioners many are now departing to fresh localities, having sold their practices and either purchased new ones or gone elsewhere to start. Practices are changing hands at all seasons of the year, but the summer and autumn perhaps witness more changes than the other seasons do. The most usual mode of commencing general practice is—among those possessed of sufficient capital to do so—to purchase one. The prices given vary a good deal with the class of practice acquired, but many fairly good-class general practices can be bought for a sum equal to the total receipts for twelve or eighteen months. The incomer has, of course, to support himself during the first year until his first bills have been paid. In good-class practices little ready money is taken. Medical agents are accustomed to gauge the character of a practice by the amount of ready money taken, *i.e.*, the more ready money taken the lower is usually the class of practice. Christmas bills, too, are often not paid until February or March. The purchaser of a practice has usually to take the lease of the house where the latter is leasehold, and is often required to purchase the furniture at a valuation. During the period of introduction he has to divide the returns with his predecessor. Bearing all this in mind it will be seen that to purchase a practice of eight hundred pounds a year requires a capital of nearly two thousand pounds.

Partnerships are much more expensive than ordinary practices, as the income is more certain and is sometimes guaranteed. Two years' purchase is a minimum price, and often much more is asked. Practices in fashionable resorts fetch more than ordinary practices. Consulting practices are rarely to be purchased, but occasionally such is the case. I have known several instances of special practices changing hands, and for very large sums. The practice of a general physician or surgeon is very rarely to be obtained thus though, and still more rarely kept if purchased, being so largely personal.

Most transfers of practices take place through medical agents, who charge a commission to venders, but none to purchasers or those seeking information. Many medical agents are either medical men themselves or related to medical men. From the number of them in London it would appear to be a good business. I have often been surprised to see so few practices advertised for sale in American medical journals. The agents' advertisements often occupy six or eight pages of our medical weekly journals. *The Lancet*, perhaps, has the largest number of this class of advertisements, being the oldest medical paper, but the other journals now have a fair share.

The bacillar origin of cholera still attracts a large share of attention. I do not think the profession here though are yet at all inclined to accept unquestioningly Koch's views on the comma-bacillus and its significance. Bacilli have been rather overdone of late years, and so many paragraphs have appeared in the journals attributing this disease and the other disease to bacilli, that sound physicians are getting rather incredulous as to some of the discoveries made by means of immersion ob-

jectives. It is not many years since Professor Klein had to recant some apparent discoveries he had made, and acknowledge that the appearances he had described were in reality due to the method of preparation and the reagents employed. I must give him credit for honestly acknowledging his error.

There can be no doubt that recent studies on micro-organisms and their relation to disease have immensely stimulated the use of antiseptics, and this, too, among many who by no means give in their allegiance to the germ theories. Carbolized vaseline has to a large extent replaced the time-honored lard in obstetric practice, and carbolic lotion is largely used in out-patient practice, even by surgeons who would never think of using the spray, and many of whom never performed operations antiseptically.

The anti-vaccination movement at Leicester is assuming serious proportions. Leicester has long been a centre of the agitation against vaccination, and for many years returned to Parliament a gentleman of very pronounced anti-vaccination views—Mr. Peter Taylor. Leicester is by no means an average town in this respect. In most parts of Great Britain there is practically no great difficulty in getting the vaccination acts carried out. It is very common for the mothers of infants about to be vaccinated to express an objection to it, on the score of the pain inflicted, and even to say they should not have their children done if they were not obliged to by law, but most of them are quite ready to acknowledge the desirability of having it done, even while expressing a sentimental objection to it. The rigid opposition of the fervid anti-vaccinationist is of a very different type. Fortunately such are not very numerous in ordinary English towns. They form a very small minority of the population, and a decreasing one. Most Englishmen have a good deal of reverence for law, and I believe the anti-vaccination movement would long since have died out but for a few fanatics who fanned the flame of discontent. I must say that when a batch of anti-vaccinationists are committed to prison for obstinate refusal to comply with the law, their voluntary martyrdom excites a good deal of sympathy even among those who differ from them in opinion, and probably does more than any amount of agitation to advance their cause among the populace at large. There is also an increasing feeling against fining the same parents over and over again. "Liberty of the subject" has always been a popular cry in England.

"DEAD TEETH IN THE JAWS."

To the Editor of The Medical Record.

Sir: In the editorial of this date, entitled "Dead Teeth in the Jaws," your suggestions as to the desirability of medical men being "better informed concerning diseases of the jaws and mouth," strike a dentist as quite *à propos;* for the public good, physicians should be better able to discriminate between "numerous harmful dental appliances" and modes of practice and the legitimate conservative treatment of diseased teeth, which is based on accurate knowledge of the anatomy and physiology of the maxillary tissues and their appendages. You do not overestimate the importance of instruction in oral surgery in the medical schools. But while the medical profession is happily beginning to realize the importance of teeth, as factors in nervous and nutritional disturbances, they should not lose sight of the value of teeth, nor of the possibilities of treatment.

"Dead teeth," so called, are not in an appreciable degree deprived of periosteal nourishment by the death of the pulp, which occupies the central canal of the root, and maintains the vitality of the dentine; the peripheral tissue of the root—cementum, histologically analogous to bone—may still be nourished in a practically normal condition by the periosteum through a lifetime, provided the latter tissue is not permitted to suffer from irritation, which is liable to be produced by the mephitic products of putrefaction of the dead pulp tissue, escaping through the apical foramen of the root. Inflammation and abscess as well as the more obscure reflex phenomena, when associated with pulpless teeth, almost invariably have the apical foramen and the periosteum about it for a starting-point; to render this point and the root-canal aseptic and preserve them in that condition by thoroughly filling the canal with impervious material, which shall prevent the entrance through the foramen of tissue fluids which would in turn become an irritant, is the aim of all intelligent treatment; and when performed with the skill and thoroughness demanded, these operations rarely fail to place the root in a perfectly benign condition. Want of knowledge, skill, or conscience on the part of dentists, unfortunately, causes too many of these operations to be harmful and often disastrous; but when the medical profession have given the attention to this subject that its importance demands, it will be able to do much more toward correcting the evil. Dr. Sexton has rendered a notable service to the profession, and to humanity, in making known the results of his careful observations of diseased teeth which, through neglect or "ill-advised dentistry," have become the cause of serious aural disturbances.

It is to be hoped that his valuable contribution and the editorial on the subject will further stimulate interest in this subject. J. Morgan Howe, M.D.S., M.D.

New York, October 4, 1884.

To the Editor of The Medical Record.

Sir: Lately Dr. Sexton has given to the profession a number of articles describing the relation between dental and aural troubles. These articles were interesting and conclusive; but the last article, in The Record of October 4th, includes a series of cases, the results of which, in several instances, are not at all conclusive. Although Dr. Sexton is to be congratulated in bringing forward this new line of thought, it must not be forgotten that this conjunction of neuralgiæ is exceedingly rare.

That poor people have bad teeth and much wax in the ears is the rule and not the exception; the teeth are allowed to decay from inability to pay a dentist; and the ears are not cleaned through inadvertency. This conjuncture of circumstances may frequently obtain without there being a connected correlation of symptoms in the two organs.

Dr. Sexton did not state, for the benefit of his readers, that it is only the middle, constricted, portion of the auditory canal that secretes cerumen nominally; the third, innermost, portion of the tube secretes cerumen only under pathological conditions; this might aid in the diagnosis.

Regarding Dr. Sexton's remarks on the prevailing practice of treating teeth, instead of extraction, we think these remarks are too sweeping, and thereby calculated to mislead a great many medical practitioners who have paid no attention to dentistry, or have even endeavored to acquire a theoretical knowledge of the dental organs. There is a good deal of imperfect work turned out by both classes of dentists, the cheaper and the more expensive ones; even extraction is often clumsily and imperfectly done; but all this, which is to be deplored, does not negative the fact that, with the exception of certain conditions (well known and rapidly diagnosed by the practised hand), it is far preferable to leave the teeth in the jaw, having the carious portion removed, than to cap, fill, build, or crown. There are several objections to extraction; the chief one, not generally appreciated, is that the corresponding tooth in the other jaw has now no opposing tooth for the purpose of mastication.

Dr. Sexton's remark on wearing dental plates is apposite; besides the danger of swallowing the teeth, or plate even (in some instances having caused instant

death), the pressure of the plate causes absorption of the palatal membrane and exfoliation of the palatine process of the superior maxillary bone in some cases; where mercury is used in preparing the cheap, rubber plates, there is danger of salivation, with possibly detrimental local results.

Dr. Sexton's remarks, that dentists leave dead teeth in, which should be extracted, are apt to lead the inexperienced practitioner to recommend a wholesale extraction of carious teeth, to the great detriment of the individual. It is an undoubted fact that dentistry has made great strides, thereby greatly benefiting the public. It is now no longer necessary to kill a nerve before filling, neither is it necessary to retain the nerve, as life and nutrition can be carried on through the peridental membrane, microscopy demonstrating the continuity of vessels through that membrane into the superfices of the fangs; lastly, bridging and crowning do away with plates.

Respectfully,

C. E. Nelson, M.D.

New York.

To the Editor of The Medical Record.

Sir: In The Medical Record of October 4, 1884, appeared an editorial upon "Dead Teeth in the Jaws," in which the practice of retaining dead or diseased teeth in the mouth is condemned. Reference is also made to the "Clinical Notes on Aural Diseases," to be found in another part of the same number of The Record, and in which Dr. Sexton is reported as also condemning the practice and charging dentists with doing more harm than good by their methods of treatment. He says: "Since dentistry has become such a popular business, and dead and diseased teeth have been so carefully retained in the jaws through their influence, especially among the better-to-do, nervous diseases about the head are becoming alarmingly common. The very general custom of wearing false teeth in the mouth attached to vulcanite, rubber, celluloid, and other plates is also an evil of vast proportions. Indeed, I sometimes think that the evil done through ill-advised dentistry is greater than the possible good arising from the work of the more capable dentists."

These are very sweeping statements, and I am sure that upon a more careful investigation they cannot be substantiated by facts. The question to determine is, What is ill-advised dentistry? In the minds of some medical men, it would seem to be the attempt at restoring dead (pulseless) or diseased teeth to a healthy condition, and that extraction of such teeth was the only safe practice. Now, against such teaching I raise an earnest protest. The cases in which trouble arises from the retention of dead and diseased teeth which have been treated by the average dentist, or from the wearing of artificial teeth, must be very small indeed in proportion to the number treated or wearing such appliances. The cause lies more in the neglect of dental treatment than in the result of it, as evidenced by Dr. Sexton's own cases. That much harm is done by ignorant dentists—and they are not a few—there is abundant proof; but that this harm outweighs the good done by the better class of dentists—who are also not a few—certainly cannot be possible. Few specialists succeed better in the treatment of disease than the better class of dentists, and it is their duty to remove an offending tooth when necessary; but their highest duty is to save it if possible.

The extraction of a tooth simply because it is pulpless, the cause of an abscess, badly decayed, encrusted with tartar, the seat of pericemental inflammation, or pyorrhœa alveolaris, etc., would be a sin against good practice; for all such conditions are in a majority of cases amenable to treatment, and should no more be sacrificed on account of their condition than that an eye should be enucleated because it was affected with conjunctivitis or ulceration of the cornea, or that a bone should be resected because at one point it was affected with caries or necrosis, or a leg or arm amputated because it was the seat of some disease which had occasionally resisted intelligent treatment. The duty of the ophthalmologist, of the surgeon, and of the dentist alike is to save the organs upon which they operate, and not to sacrifice them. The latter procedure would be many times less troublesome to the operator and the shortest way out of the difficulty for the patient; but it would not be based upon sound surgical principles, it would not be common sense, nor would it be right.

To the minds of many people the teeth are of but little consequence, and I am sorry to say their value is not properly appreciated by many physicians, if one may judge from the advice often given to their patients, viz., "If a tooth troubles you, have it extracted;" and with equal propriety they might say, if your eye troubles you, have it taken out—but no surgeon would be justified in doing it, save as the last resort.

That there is great need of a higher educational standard among dentists is freely admitted. In fact, it has been the firm conviction for years of many in the profession that the dental surgeon should be regularly educated in medicine before taking up the study of his specialty; that he should go through the same course of preliminary training insisted upon by the specialist in other branches of medicine; and that the purely mechanical part of dentistry (the making of artificial teeth) as now practised should be divorced from it and relegated to the artisan, thus giving the dentist opportunity to devote his entire time to the study and practice of the scientific department of his calling. It is also a fact that there is great need that medical men should be better educated in the pathology and treatment of dental and oral diseases, for the great majority are lamentably deficient in knowledge upon these subjects.

To this lack of knowledge may be attributed the unsound advice often given in relation to the diseases of the teeth and oral cavity, as well as very many of the failures to diagnose the cause of certain apparently obscure diseases of the eye and ear and neuralgias of the face and head, while, had the dental surgeon received the proper training in this direction, he would have been able many times to determine whether or not it was located in an offending tooth or caused by some other oral disease.

The formation in the American Medical Association of a Section on Dental and Oral Surgery four years ago, and the more recent establishment of instruction in oral surgery in some of the medical colleges, are expressions by the representative medical men of our country of the value and need of better instruction upon these topics, and an effort to supply it.

It is to be hoped that the movement will receive the encouragement it deserves.

I am very truly yours,

John S. Marshall, M.D.

242 Wabash Avenue, Chicago, Ill.

TUBAL PREGNANCY.

To the Editor of The Medical Record.

Sir: Dr. Mundé finishes his article on his case of extra-uterine pregnancy, in the issue for September 27 of this journal, with some considerations as to what becomes of the incysted ovum after the fœtus has been killed by electricity. As a contribution to the answer to this question I would state that I had the opportunity to examine the patient upon whom I had performed this operation in 1882 (see "Transactions of the American Gynecological Society," vol. vii., p. 185) two years later. She had grown considerably stouter, and had never become pregnant. She enjoyed perfect health, and the only thing she complained of was that she had no venereal orgasm during intercourse, although her husband is a healthy young man and nothing abnormal with regard to

the act could be discovered in him. In spite of the increased amount of fat in the abdominal wall, the pelvic organs could be distinctly felt by bimanual palpation. The uterus was found anteflexed as at the time of the operation, but placed in the median line, and there was no trace left of the tumor in the right Fallopian tube.

Yours truly,

H. J. GARRIGUES, M.D.

168 WEST TWENTY-THIRD STREET, NEW YORK.

THE REASON WHY ST. LUKE'S HOSPITAL DOES NOT FURNISH MEDICAL HISTORIES TO OUTSIDE APPLICANTS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: My attention has been called to a communication in your issue of this date, from Dr. Joseph P. Fessenden, of Salem, Mass. It contains my correspondence with that gentleman, in which, on behalf of this hospital, I declined to give information concerning the disease with which a recent patient suffered while under our care.

In your editorial note on the same, you say that "it is difficult to understand upon what grounds any public hospital can refuse to give to a medical gentleman such information as was solicited," and you courteously request some explanation on this point from the hospital authorities.

The answer to your question involves the important point as to the rights of patients who enter our hospitals for treatment.

Dr. Fessenden's position, as I understand it, is that the confidential communications which our patients make to our doctors concerning their own diseases and the causes which led to them, and our physicians' diagnosis and method of treatment (which are all matters of record in the Medical History Books of the hospital), should in all cases be at the disposal of any physician who asks for them, as a guide to his own subsequent treatment. This position, I hold, cannot be maintained.

In cases of litigation, the attempt has not infrequently been made to obtain from this hospital voluntary information concerning the private character and diseases of either present or former patients, for the purpose of aiding some prosecuting attorney. Such information has uniformly been denied, on the ground that the communications of our patients to our doctors are confidential, are made for purposes of intelligent treatment by our doctors of their individual case, and are not public property. So frequently were such requests made that in 1881 I requested the Counsellor of the Corporation to define clearly my duty in the premises, and received from him the following: "In a litigation where a patient of the hospital is a party, I do not think it would be right for the hospital to disclose to the opposite party, from its books, or through its physicians, facts relating to such patient learned through the connection of such patient with the hospital, unless such disclosure be required by process of court under the ordinary rules of evidence relating to such matters. There might, however, be an exception to this rule in a criminal matter, when the information was requested officially by the District Attorney."

This has established the following rule for the administration of this hospital: that when there is any reasonable ground to question whether the information sought would or could in any way be used to the disadvantage of the patient, it is to be studiously withheld, unless our hospital records are called regularly into court as evidence, when we are obliged to testify to "the truth, the whole truth, and nothing but the truth."

The facts in regard to the case referred to by Dr. Fessenden are that on September 9th I received a letter from a stranger in Salem, Mass., asking, among other things, "the cause of Mr. B——'s being in the hospital." I replied, stating the fact that Mr. B—— had been a patient here, and giving the date of his entry (March 4th) and his discharge (April 14th) as "cured," but declining to disclose the disease from which he suffered, and giving the reasons why such communications could not be made. On September 16th I received a letter from Mr. B——'s brother in Boston, making similar inquiries, and asking if I thought his brother's "brains were all right," that "he talked and acted very strangely." A similar reply was sent. Again, on September 20th, I received a letter from a Dr. Fessenden, who was unknown to me, in which he says: "Mr. B—— is now with his sister in Salem, having suddenly appeared after an absence of six years, physically much emaciated, almost in rags, and mentally unsound besides. I would like to know what was the matter with him while at St. Luke's, and whether he was in sound condition when he left."

Judging from all the circumstances of the case, I could not doubt that Mr. B—— had proven an unwelcome guest on his return to Salem, that it was the desire of his family to send him to a lunatic asylum, and that the physician who had already concluded that his patient was "mentally unsound" sought corroborative evidence from this hospital. This, in justice to our former patient, I felt I must decline to give. My conclusion as to the reasons which prompted the inquiry are reinforced by my published letter to Dr. Fessenden, in which is stated, at least inferentially, my willingness to communicate the facts to Mr. B—— himself, or at his request to his physician.

Yours respectfully,

GEORGE S. BAKER,
Pastor and Superintendent.

ST. LUKE'S HOSPITAL, NEW YORK, October 11, 1884.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 5 to October 11, 1884.

CLEMENTS, B. A., Major and Surgeon. In addition to present duties, to take charge of the office of the Medical Director of the Department during the temporary absence of that officer. S. O. 195, par. 1, Department of the Missouri, September 29, 1884.

HAPPERSETT, JOHN C. G., Major and Surgeon. Will be relieved from duty in Department of the East and ordered for duty at Willet's Point, N. Y. S. O. 235, A. G. O., October 7, 1884.

WOODRUFF, EZRA, Captain and Assistant Surgeon. Granted leave of absence for four months. S. O. 235, A. G. O., October 7, 1884.

CRONKHITE, HENRY M., Captain and Assistant Surgeon. Assigned to duty as Post Surgeon, Fort Reno, Indian Territory. S. O. 197, Department of the Missouri, October 2, 1884.

LORING, LEONARD Y., Captain and Assistant Surgeon. From Department of the East to Department of California. S. O. 237, A. G. O., October 9, 1884.

HARVEY, PHILIP F., Captain and Assistant Surgeon. From Department of Dakota to duty in Attending Surgeon's Office, Washington, D. C., relieving Robert W. Shufeldt, Captain and Assistant Surgeon, who, on being relieved, will report to Commanding General Department of the Missouri for duty. S. O. 237, A. G. O., October 9, 1884.

POWELL, J. L., Captain and Assistant Surgeon. Granted leave of absence for one month on surgeon's certificate of disability. S. O. 204, Headquarters Department of the East, October 8, 1884.

SPENCER, WM. G., Captain and Assistant Surgeon. Granted leave of absence for one month. S. O. 204, Headquarters Department of the East, October 8, 1884.

McCREERY, GEO., First Lieutenant and Assistant Surgeon. Assigned to duty at Fort Meade, D. T. S. O. 115, Headquarters Department of Dakota, October 6, 1884.

TAYLOR, A. W., First Lieutenant and Assistant Surgeon. Assigned to duty at Fort Omaha, Neb. S. O. 87, par. 3, Headquarters Department of the Platte, October 3, 1884.

BLACK, C. S., First Lieutenant and Assistant Surgeon. Granted leave of absence for fifteen days, to take effect this date. S. O. 131, par. 3, Department of Texas, September 29, 1884.

Official List of Changes of Stations and Duties of Medical Officers of the U. S. Marine Hospital Service, July 1 to September 30, 1884.

BAILHACHE, P. H., Surgeon. To proceed to Delaware Breakwater Quarantine Station as inspector, September 10, 1884, to investigate reported pollution of Potomac River water-supply, September 20, 1884.

MILLER T. W., Surgeon. Granted leave of absence for fourteen days, July 10, 1884. Detailed as President Board of Examiners, September 2, 1884.

WYMAN, WALTER, Surgeon. Detailed as Member Board of Examiners, September 2, 1884.

LONG, W. H., Surgeon. Granted leave of absence for twenty days, July 30, 1884.

PURRIANCE, GEORGE, Surgeon. Detailed as Recorder Board of Examiners, September 2, 1884.

STONER, G. W., Passed Assistant Surgeon. To proceed to Lewes, Del. (Delaware Breakwater), as inspector, July 25, 1884. To act as Quarantine Officer at Delaware Breakwater, July 31, 1884.

FISHER, J. C., Passed Assistant Surgeon. Granted leave of absence for thirty days, August 21, 1884.

GOLDSBOROUGH, C. B., Passed Assistant Surgeon. Granted leave of absence for thirty days, July 12, 1884. Leave of absence extended thirty days on surgeon's certificate of disability, August 11, 1884. Leave of absence extended thirty days without pay, September 11, 1884.

HEATH, W. H., Passed Assistant Surgeon. Granted leave of absence for thirty days, September 8, 1884.

GUITÉRAS, JOHN, Passed Assistant Surgeon. Granted leave of absence for thirty days, September 24, 1884.

BANKS, C. E., Passed Assistant Surgeon. Granted leave of absence for thirty days, August 27, 1884.

BENNETT, P. H., Assistant Surgeon. To proceed to Buffalo, N. Y., for temporary duty, September 19, 1884.

GLENNAN A. H., Assistant Surgeon. To proceed to Mobile, Ala., for temporary duty, July 7, 1884.

FISHER, J. C., Passed Assistant Surgeon. Resignation accepted by the Secretary of the Treasury, to take effect September 30, 1884. August 21, 1884.

THE PAY OF THE MEDICAL DEPARTMENT DURING THE REVOLUTION is given by a writer in the *Magazine of American History* as follows: "To the office of Director of the Military Hospitals was attached the pay of $150 per month, two rations, one for servant, and two of forage; to that of the chief physician and surgeon of the army, $140 per month, two horses and wagon, and two rations of forage; to each of the three chief physicians and surgeons of the hospitals, $140 per month and two rations; to the purveyor, $130, and his assistant, $75 per month; to the apothecary, $130 per month, and his two assistants, $50 per month each; to the fifteen hospital physicians and surgeons, $120 per month each, and to each of the twenty-six mates, $50 per month."

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 11, 1884:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.

INFLUENCE OF SYPHILIS AND MERCURY ON CHOLERA.—M. Martineau has investigated the influence of syphilis and mercurial preparations on cholera. His inquiries lead him to believe that syphilitic patients under mercurial treatment are not exempt from cholera. In 1849 and 1865 the wards of the Lourcine Hospital were full, and the mortality from cholera was excessive there. M. Dujardin-Beaumetz says that syphilis has a fatal influence on typhoid fever. The patients from the Lourcine and Midi Hospitals seized with typhoid fever are sent to the Cochin Hospital, where it is the prevalent opinion that syphilitic patients attacked with typhoid fever have received their death-warrant.

PEPTONIZED MILK.—In reply to the questions raised by Dr. N. E. Oliver in a previous issue of THE MEDICAL RECORD concerning peptonized milk, a correspondent writes that there is no necessity for the use of the *soda* in peptonizing milk. If two portions of milk be prepared —one with soda and the other without—no difference can be seen in the action of the pancreatic ferments, and they will both be digested in the same time. The pancreatic ferments act upon all food substances without the need or use of "alkali." In digesting milk it is necessary to check the action at the desired stage. It was originally proposed by Dr. Roberts to do this by bringing the heat to the boiling point, thus killing the ferment. But if peptonized milk is boiled at any period short of the complete conversion of the caseine into peptone, it is coagulated. This coagulation is due to the peculiar substance into which caseine is changed in the process of its conversion into peptone. The addition of soda bicarbonate was found to prevent this reaction, so that digestion may be checked by boiling at any stage of the digestion, when soda is used. The writer proposes the chilling of the milk by ice to check the digestion and maintain at any desired point, still preserving, however, the *vitality* of the digestive agent. Is the soda objectionable? is it in "excess?" The milk-curdling ferment acts upon alkaline milk (up to 15 grains of soda to the pint) just the same as upon pure milk, but not so quickly. Woman's milk is alkaline. The stomach has two resources for the coagulation of milk—the acid and the milk-curdling ferment. Therefore the soda as used can hardly be considered excessive. There is no doubt but that the coagulation of the milk in the stomach places the digestion of the albuminoids of milk upon the same footing as other albuminoids. So it would seem a self-evident proposition that in order to render cow's milk a fair daily food for the average infant, as a substitute for its mother's milk, it should first be made to quantitatively approximate thereto, and then the caseine adequately altered. When this is done the milk *does curd* in the stomach, or by the addition of acid, precisely as does human milk—namely, in minute flocculi. In cases of disease of the digestive tract,

how far it is proper to pre-digest the caseine, and how long to continue the exhibition of thoroughly pre-digested milk, is a question not within the province of the writer. In order to use the milk at night, the peptonizing agent can be put into a bottle with half a pint of cold water, half a pint of cold milk, and four tablespoonfuls of market cream. Shake, and place on ice at once. There will be no digestive action in this situation. When needed, pour out just enough for a feeding into a tin cup and hold over a brisk flame for six minutes, stirring constantly with a spoon and tasting often so that it does not become too hot to be sipped. Now pour into a nursing-bottle and it is ready for the child. When ice cannot be conveniently had, put four tablespoonfuls of cold water into a tin cup and the proper proportion of peptonizing powder. Mix well and add four tablespoonfuls of cold milk and one of cream, and hold over a flame for six minutes, stirring constantly and tasting so that it does not become too hot to be sipped.

What Quacks Can Do.—Dr. D. B. Smiley, of Middletown, N. Y., writes that two "eclectic" physicians in that town recently undertook to deliver a parturient woman, and did the work in fifteen minutes. The head was seized with the forceps, a towel wound round the neck, and both the quacks gave a long pull together. Result: the head was pulled off! The body was then turned and delivered. The result was that the vagina and perineum were torn to shreds, and the patient died next day. An inquest was called, and the two quacks testified that, though the urine had not been passed for twenty-four hours, they had not thought it advisable to draw the water. One of them stated that the woman's temperature, as taken with his finger, was 93° or 94°. This one stated that the normal healthy temperature was 76° or 80°, but might be 140°. He stated that he meant blood-heat, not the pulse. The other was not altogether clear, but believed 70° to 80° to be about fair, and that it was higher in our Southern States. He used instruments; an instrument for the purpose was called a barometer. The cause of death was given in the death certificate as "uterine paralysis." The coroner's jury returned a verdict that the death was caused "from childbirth, superinduced by over-protracted labor and a want of proper care anterior thereto, and that, in some respects, there was had unskilful practice upon the part of the attendant physicians in the case." The physician who gets such surprising results with a barometer registers as having a diploma from the Eclectic Medical Society of New York, October 17, 1877. It would be interesting to learn on what kind of an examination that Society grants its diplomas, and whether the barometer is in general use among eclectics, and under what circumstances they decide that a patient has fever; also, whether they are proud of their graduates.

Gastric Hysteria.—Dr. G. Frank Lydston, of Chicago, Ill., sends an account of a curious case. We fear that his diagnosis will be disputed, especially in view of the death of the patient. Hysterical vomiting or gastric hysteria would more likely cover the case.

"Annie K——, sixteen years of age, living at home with her relatives, who were in rather moderate circumstances. The young lady had always been perfectly healthy up to the age of thirteen, when she began to have periodical attacks of epistaxis, attended by severe pain in the lower part of the pelvis and back. These attacks occurred at intervals of about three weeks. Eight weeks before I first saw the case, she had one of her usual attacks, but in addition was affected by severe and uncontrollable vomiting. She was seen by several physicians, most of them, I believe, being of the homœopathic persuasion. A number of diagnoses had been made, the most prominent being gastric ulcer, cancer of the womb, and ulceration of the womb. It appeared upon inquiry that an elder sister of the patient had died from a similar sickness, the nature of which had never been determined. On examination I found the patient considerably emaciated (no aliment had been retained by the stomach for eight weeks, and rectal alimentation evidently had not been thought of) and very restless from nervous exhaustion. On examining the ejecta, I found them to contain a considerable quantity of bile, but no blood. There was no pain in the epigastric or intrascapular regions, but a great deal of pain in the limbs and head was complained of. The temperature was normal. Very slight tenderness over the lower part of the abdomen, which was probably exaggerated by the extremely nervous condition of the patient. On examining the uterus, I found it to be very small, particularly as regards the body of the organ. There was no neoplasm or other morbid condition. The ovaries could be felt very indistinctly. I accordingly made the diagnosis of reflex uterine vomiting, dependent upon non-development of the uterus and ovaries. On the third day after my first visit, I succeeded in checking the vomiting, I having meanwhile attempted to support the patient by nutrient enemata. After the vomiting stopped, koumiss and small quantities of brandy were retained by the stomach. At my last visit on the evening of the third day, restlessness and nervous irritability seemed to be increasing, although the pulse was stronger and less frequent. Shortly after I left the house, however, the patient requested her friends to leave the room for a while as she wished to sleep. Accordingly she was left alone for about five minutes, and when her friends returned they found her dead. At the autopsy, which was readily obtained, the stomach and other abdominal viscera were found to be perfectly normal. The uterus and ovaries were rudimentary, the former measuring about one and a half inch in length, and the latter being about the dimensions of good-sized beans. The sexual organs were otherwise normal, with the exception of a peculiar ring of dilated capillaries surrounding the os uteri externum. This was of a bright red color, which persisted in the specimen until placed in preservative fluid."

The Hemorrhoid Quack.—Dr. B. N. Stevens, of Chillicothe, Mo., writes: "We have a class of 'quacks' in this part of the country that advertise to cure hemorrhoids without pain, and that they meet with more or less success is proved by their patronage. You cannot get a patient here to submit to the knife or ligature. They say they will go to the man who can cure them without pain, and whose treatment does not require them to be laid up. Now, of course, they use injections. Will you give your experience with them, the *modus operandi*, etc. ?" We can only say to this that Dr. Stevens will find full descriptions of the carbolic acid treatment of piles in recent works on surgery or diseases of the rectum. The treatment is often efficient, but not entirely free from danger.

Not Extra-Uterine Pregnancy but a Dermoid Cyst.—Dr. Leonard D. White, of Uxbridge, Mass., writes: "In your paper of August 23, 1884, I noticed a short article from the pen of G. C. Park, of Murraysville, Pa., and headed 'Extra-Uterine Pregnancy,' etc. Judging from the description alone, I wish to ask if the tumor under consideration might not more properly be classed under the head of 'Dermoid Cyst.'" Dr. Park in a subsequent note admits that the diagnosis of dermoid cyst is probably the correct one.

The Florida Climate.—Dr. H. A. Canfield, of Gillmore, Pa., writes that his experience regarding the value of the Florida climate has been more in accord with that of Florida physicians than that of Dr. Boyland. Dr. Canfield and Dr. Boyland, from the latter of whom we have received a letter dated September 17th, agree in urging the plan suggested by Dr. Lancaster, of securing an investigation of the Florida climate by a committee of the American Medical Association.

CONTRIBUTIONS TO

THE ANATOMY OF THE LEMNISCUS.

WITH REMARKS ON CENTRIPETAL CONDUCTING TRACTS IN THE BRAIN.

BY E. C. SPITZKA, M.D.,

PROFESSOR OF NEURO-ANATOMY AND PHYSIOLOGY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

(Continued from page 427.)

III.

In the carnivora the relations of the pes and the lemniscus are much more intimate, owing to the lesser development of the ganglion of Soemmering and the non-intervention of transverse pons fibres. In a set of transverse sections from the brain of a lioness, it can

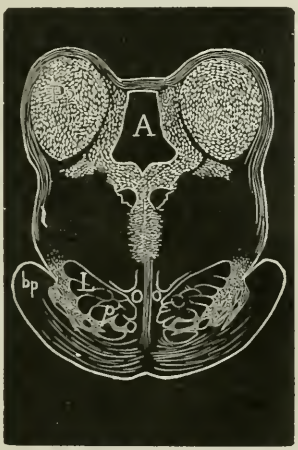

FIG. 13.—Transverse Section through Posterior Pair of Corpora Quadrigemina and Anterior Part of Pons of a Lion. A, aqueduct; P2, ganglion post-optici; *l*, lemniscus portion to same; L, main part of lemniscus; *p*, pes fibres; *bp*, *pontis-brachium*.

be clearly seen how the middle lemniscus area (L, Fig. 13), which is all along separated by a molecular interval from the lateral division (*l*) that goes to the post-optic lobes (P2), constitutes a united bundle with the pes. They are not separated even by a connective-tissue septum, and while confirmatory sagittal sections have not been made, it seems from the comparative area, that the lemniscus portion enters into some union with the substantia nigra and with the subjacent part of the pes. Aside from this connection, the bundle from the pes to the lemniscus (pedal part of the (intermediate) interolivary stratum), represented by the O-like areas on both sides of the raphe, is a well-marked feature of the lion's brain.

In the cat there is a connective-tissue intercalation between the pes and the lemniscus, and it is difficult to decide from tranverse sections whether the main division of the lemniscus is in part absorbed by the ganglion of Soemmering, or lies dorsad of it or in the pes. Certainly there is no correspondingly well-marked field as that represented in L, of Fig. 14 (a section from the human mesencephalon); although in lower levels the lemniscus is quite as distinct, though not as large as in man and the apes.

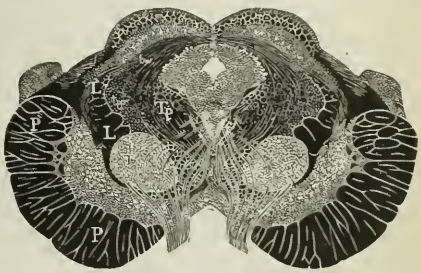

FIG. 14.

In the lion there is a slight separation between the horizontal main lemniscus and the bundle from the pes to the lemniscus of Wernicke (pedal part of stratum intermedium); in the cat the two approach more closely, and the latter constitutes an angle (open dorsad and laterad) with the horizontal expanse of the former. A fortunate set of sagittal sections from a cat reveals a remarkable confirmation of the course of this fasciculus in the dog, as well as an interesting relation to the trapezium. The main part of the stratum interolivare breaks up into numerous bundles, ramifying and meandering among the transverse bundles of the trapezium, thus producing a beautiful wickerwork pattern,[1] at the cephalic end of the trapezium field they re-collect and run exactly in the situation of the bundle from the pes to the lemniscus (to the "tegmentum" of Henle). The following differences are noted from the case of the human subject: 1. The bundle does not connect as abundantly with the ganglion of Soemmering; perhaps this indicates that the apparent relation with it, in man, is a spurious appearance. 2. But a small part joins the pes permanently; the main part is in juxtaposition for a part of its course only, it leaves it to radiate under and mesad of the nucleus tegmenti (perhaps in part entering it) to take a course which only basi-parallel sections can expose (see dog).

In his latest work[2] Meynert says: "Where these bundles of the internal capsule (certain intertwined fasciculi from the cortex—in the diagram to be referred to he changes about and derives them from the lenticular nucleus) run in the same height as the opposite *pes pedunculi* (he means the proximal internal part), they admit processes of the *substantia nigra Soemmeringii*, with which they are soldered into a compact layer behind the superficial layers. Where this fibre layer of Soemmering's substance, which I term *stratum intermedium pedunculi*, covers the tegmentum of the crus, it is bulged forward by the subjacent red nucleus of the tegmentum. In its further course the *stratum intermedium* exhibits a concavity applied to the biconvex deep mass of transverse

[1] This is one of the prettiest pictures in cerebral histo-anatomy, the *stratum intermedium* fibres bear an analogous relation to the transverse lemniscus, as the sagittal fibres of the pons bear to the transverse ones in man. There are not the same mediating nucleur intercalations. Near the main height of the trapezium there is a beautiful set of cells, not hitherto described, these are scattered in the meandering fibres in the more dorsal division, and of considerable extent. Not all the meandering fibres appertain to this stratum, the dorsal third or more, are derived from the reticular field of the oblongata.

[2] Psychiatrie, p. 48.

fibres of the pons, and in the oblongata appears to lie behind the pyramids as the most anterior layer of the anterior column, and internally to the olive."[1] He disconnects the lemniscus from the stratum intermedium, with which I agree in thinking that it should not be confounded.

This description corresponds in many features with the one I have attempted to give. It is singular that in the most obscure part of this tract Meynert should agree with the most modern authorities so nearly, and yet differ in regard to the simplest and earliest known part of its course in a territory with which he showed himself in his earlier work to be thoroughly familiar. His plate of the spinal cord (page 124, loc. cit.) only the eminence of its author saves from the epithet "puerile." He allows the interolivary stratum intermedium to pass *without any decussation* into the anterior column of the cord, occupying the field correctly assigned by Flechsig to the undecussated part of the true pyramids. He emphatically declares that the pyramids decussate *in toto*, so that there is no other explanation for his mistake than to suppose that he sticks the (interolivary) stratum intermedium where he loses it, to the undecussated part of the pyramid tract, where he picks the latter up; its upper origin he either ignores or is unacquainted with. The latter alternative is contradicted by a clause in his older (and for its day superior) treatise in Stricker's collection. The true course of the *stratum intermedium* (proven beyond question by the secondary degeneration of my case) in the piniform decussation still passes as a decussation of external pyramid fibres, with a slight doubt. This adhesion to the old error, worse confounded by the attempt to implant it on more modern views, is utterly incomprehensible.[2] It is true that some fibres take the course claimed by Lockhart Clarke, and after him by Meynert, but if the development and atrophy methods (of which the secondary degeneration is one) are entitled to a moment's consideration, they prove that the great mass of the stratum intermedium passes to the nuclei of Goll and Burdach, and that the admixture of pyramid fibres is slight. I have, in an earlier part of this article, referred to the topographical misunderstanding on this head.

There is no warrant for the designation of the direct myelo-cerebellar tract by Meynert as "lemniscus inferior" (from the cerebellum). Meynert's description had been superseded by Flechsig, who is entitled to the credit of its discovery (with Foville). His refusal to accept Flechsig's name may be a protest against the animus of Flechsig's warfare; if so, it is a singular one. If we include Meynert's *stratum intermedium*, the alleged pyramid tract in Goll's columns, the direct myelo-cerebellar tract, and the outer part of the anterior lateral column under the term lemniscus, we cover pretty much the entire periphery of the cord from the bottom of the anterior fissure round to the corresponding part of the posterior.[3]

The only tract which is correctly entitled lemniscus in Meynert's plate is the "lemniscus superior." It is greatly exaggerated, however, and he who is familiar with the results of Flechsig, which are accepted by nearly all neurologists, must be puzzled[4] on seeing this superior lemniscus made to cover a good half of the periphery of the cord, while the direct myelo-cerebellar tract covers just one-tenth as great an area. In truth, the relation is nearer the reverse. In Mayer's case there was secondary degeneration of the (true) lemniscus. As the case was of but a year's standing, it may not have covered all the area it might have ultimately extended over; it was situated in a line of prolongation intermediate to the lateral and anterior cornua, and at the periphery. The myelo-cerebellar tract, on the other hand, covers a large segment of the cord.

IV.—The Trineural Fasciculus.

Several years ago[1] I maintained that the so-called round bundle of Clark and solitary bundle of Stilling was not, as Krause claimed, directly derived from the spinal fibres of the same side. I derived it in the main from the piniform decussation, which, as direct anatomical observation and other methods referred to in the foregoing show, is a direct continuation of the stratum intermedium (interolivare). At that time, following Meynert, I regarded a larger part of the lemniscus as derived from the ganglia of the posterior pair of the corpora quadrigemina than is now done, and consequently supposed that these ganglia through the discovered connection, exerted their influence on vegetative life. The trineural fasciculus comprises a system of fibres imbedded in ganglionic substance, into which numerous of the internal arciform fibres can be traced. In the major part of its course it is constantly in receipt of new fibres through this ganglionic medium, and expends others which become roots of origin of the *nervus intermedius* (an aberrant branch of the glosso-pharyngeal, see Bigelow's and my own communications to The Medical Record of 1880), the *n. glosso-pharyngeus* and the *n. vagus*. Most authors add the spinal accessory to the list. In my earlier communications I held a reserved position on this head, but not venturing to contradict what was then the unanimous opinion, allowed but a minimum of its fibres to that nerve. Mendel, in a discussion with Wernicke, held in Berlin, denied such a connection *in toto*, not only for the accessory but also the vagus nerve; this I think is going too far. The vagus does receive rootlets from this fasciculus. On the other hand, I endorse his view, as against Wernicke, that the accessory is not so connected. I am not able to declare as positively as Mendel does, and as I did in the communications referred to, that the trineural fasciculus ends at the level of the gustatory nerves. It is not impossible that a slender prolongation continues on to the substantia ferruginea (locus cæruleus), though this is a mere suspicion with me at present.

As I maintained that the trineural fasciculus is a recurrent branch of the lemniscus tracts, its description is germane to our subject. My reasons for opposing Krause's view that it is exclusively a respiratory fasciculus (Respirations-Bündel) are the following:

1. It extends with undiminished diameter beyond the level of the pneumogastric nerve and distinctly connects with the glosso-pharyngeal and intermediate nerves.[2]

2. If the trineural fasciculus came from the cord, its origin would (Fig. 14) be very near the median line, in districts which we know have other destinations.

3. The fasciculi of both sides approach each other very closely, suggesting a decussation.

4. They or rather their ganglionic "sheaths" continually receive arciform fibres. These arciform fibres cross the raphe, and while many running in this direction are from the reticular formation, the majority come from the olive and the stratum interolivare.

5. While it is not impossible that, the decussation being established, such decussation may be from below—

[1] The above is a specimen of Meynert's language, and may serve to indicate the difficulties under which the translators of his anatomy labored. In plain English a free and logical rendition, embodying a consistent use of topographical terms, would be: "From the cortex, a flat layer of fibres converges toward the *substantia nigra*, being interpolated between it and the tegmentum as an *intermediate stratum*. The nucleus tegmenti, dorsad of it, causes a ventrally convex depression. After an admixture with the processes of the *substantia nigra*, this tract courses over the dorsal pons fibres, being concave in correspondence with the convex contour of the latter. Below (caudad of) the pons, it seems to lie immediately over (dorsad) the pyramid in the triangular field, between the latter, the olive, and the raphe.

[2] There is not the slightest reference to the results yielded by a study of secondary degeneration, though Mayer's, Homén's, and my cases were published between one and two years prior to the appearance of Meynert's last work.

[3] To characterize the diagram in question further, it may be stated that it is—where not absolutely erroneous—imperfect and theoretical. It does not correspond to the present state of science, and must prove a serious disappointment to the numerous students and admirers of Meynert.

[4] If the abnormally diminutive pyramid be erased, and the designations of the lemnisci reversed, Meynert's diagram may be turned up-side down, and will gain by the inversion, inasmuch as the uncrossed part of the pyramid, and the stratum intermedium will then come out right, while the deeper fissure will occupy the correct dorsal (posterior) position.

[1] Chicago Journal of Nervous and Mental Diseases, 1879.

[2] Duval discovered the connection of the *nervus intermedius* with the nucleus of the glosso-pharyngeal, and I demonstrated an additional origin from the trineural fasciculus. Unfortunately the chief specimen was ruined in class demonstration, so that I am unable to test some new questions that have arisen, as to the continuation of the fasciculus farther, or as I then taught, its cessation at this level.

that is, from the cord, upward, and not, as I maintain, from above (cephalic), across the median line and reflected back upward (cephalad) again—the direction of the arcuate fibres is against that view.

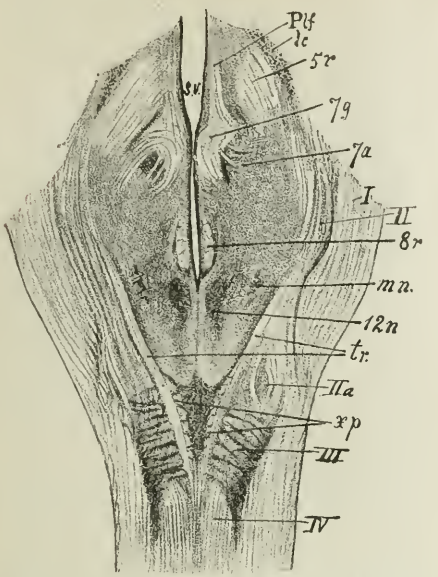

FIG. 15.—Section Parallel to the Floor of the Fourth Ventricle of Man. (Autopsy through Professor Little.) *sv., sulcus ventriculi quarti; lc*, locus cæruleus cells; *5r.* the enormous raphe root of the sensory division of the trigeminus; *7g, genu* facialis; *Plf*, posterior longitudinal fasciculus (oculo-nuchal co-ordinator); *7a*, ascending fibres to join raphe root; *I*, cerebellar myelobrachium, or posterior peduncle; *II*, fibres of reticular formation ascending in tegmentum; *8r, striæ* root of auditory, imbedded in its (?) nuclear substance; *mn*, nuclear mass of mixed system; *12n*, nucleus of hypoglossal nerve; *tr*, trineural fasciculi; *xp*, ganglionic processes, including fibres from the piniform (sensory) decussation; *III*, bundles of latter divided across in their ascension.

6. Direct observation shows that the lowest demonstrable fibres come directly from the processes of the piniform decussation. Occasionally a process is seen running outward, but it cannot be traced far, and transverse sections show that many rootlets passing from without inward and over the fasciculus, are only curved around, taking an arched course from the same decussational origin. All clear appearances demonstrate a connection with the decussation.

The fibres, although regarded of similar optic appearance in transverse sections, show two well-characterized varieties in lengthwise sections. The axis of the bundle is composed of thicker fibres with broad myelin sheaths which have a pale tint in the aggregate, absorbing little carmine; the surrounding fibres are finer, and in bulk fairly well stained, resembling the bundle which passes from the habenula to the outer peduncular ganglion [1] in this histological respect. In sections of the same direction as the one represented in the figure, the core bundle is not smoothly continuous, but interrupted, as if it consisted of slightly arched fasciculi, which may emerge at various points in the course of the fasciculus. The difference in the character of the fibres would indicate that the trineural fasciculus acts as a conductor for several functions.

In the case of secondary degeneration of the stratum intermedium, the functions of the mixed nerves, as far as deglutition was concerned was impaired. This fasciculus was healthy, but many of the arched fibres going to it were not—they had undergone degeneration. One fasciculus crossing out from the raphe, four or five "branches" distant from the hypoglossal nucleus (that is, very near the dorsal end of the raphe) was entirely healthy (Fig. 3, *t*; also Fig. 4). From the course of its bundles in the raphe, and its freedom from degeneration, it cannot come from the interolivary, but from the true olivary and reticular field portion of the lemniscus. The fact that this fasciculus is larger in the level of Fig. 4 than that of Fig. 3 proves conclusively that if there is a spinal origin for this bundle it must be a very subsidiary element.

Internal to the trineural fasciculus there are a number of separate fasciculi, continuous for as great a length and apparently originating in a similar manner. They are very clear in flat-wise sections and apt to be altogether overlooked in transverse ones. They cannot in higher levels be confounded with the longitudinal bundles running in the hypoglossal and vagus nuclei in lower levels, referred to by Mendel, though I am not prepared to deny a connection between them in the said lower levels.

(To be continued.)

[1] In an earlier day of cerebral anatomy, the fact that the stratum interolivare becomes lost in about the same region where a part of Meynert's bundle runs would have been regarded as suggesting a connection.

DISEASE GERMS.[1]

BY GEORGE M. STERNBERG, M.D., F.R.M.S.,
MAJOR AND SURGEON U. S. A.

IT is but a few years since "disease germs" were hypothetical things, in regard to the origin, nature, form, and *modus operandi* of which we possessed only vague and uncertain notions.

In this pre-scientific peroid of etiological inquiry, a favorite idea with those who assumed the existence of disease germs on theoretical grounds was that they are living particles detached from the diseased organism, capable, perhaps, in some instances, of self-multiplication external to the body, and having the power, when introduced into the body of a susceptible individual, of inducing morbid phenomena identical with those which, in a preceding case, were the cause of their origin. In other words, that they are both the cause and the result of the morbid phenomena which characterize the specific infectious diseases.

No experimental evidence has thus far been adduced in favor of this conception of disease germs, which is evidently unphilosophical, and is unsupported by observation or analogy. The only detached living particles known to science which are thrown off from the bodies of plants and animals, and which are capable of subsequent development, are the reproductive elements, the function of which is to preserve the species and not to destroy it; and observation teaches that as a general law disease is due to agents introduced from without, whereas the view above referred to would necessitate a belief in the intrinsic origin of the specific infectious diseases. For there could be no disease germs detached if there were no diseased organism to throw them off.

But the progress of science has made us acquainted with disease germs of another kind, which being *vegetable* parasites must in the first instance have been of extrinsic origin, even if at present they have, in certain cases, no other habitat than within the body of the animal in which they produce specific morbid symptoms.

Thus, if it be demonstrated—a very difficult matter, by the way—that the tubercle bacillus is found only in the tubercular products which result from its invasion of the bodies of man and the susceptible lower animals, it will be none the less improbable that this has always been the case. We must admit that this bacillus existed in nature before there was any tuberculosis, or we are forced to one of two conclusions: either the disease tuberculosis at one time occurred independently of the bacillus, or the parasite was created as it now is and implanted in the bodies of animals especially to produce this disease. The second alternative involves the acceptance of a theoretical conception which cannot be discussed from a scientific standpoint. It is evidently opposed to

[1] Read at the meeting of the American Public Health Association in St. Louis October 17, 1884.

the scientific conception which has forced itself upon careful students of nature in all parts of the world, and which is expressed in the word *evolution*.

If at any time in the past the disease tuberculosis existed independently of the tubercle bacillus, or of any other micro-organism, then we must deny that this parasite has any etiological import, or must at least assign it a secondary rôle, viz., that of carrying a non-living tubercle virus from a diseased organism and implanting it in a new soil. In this case the infectious character of the disease would depend upon the living parasite; but inasmuch as the disease must at some time have originated independently of the parasite, we could scarcely deny the possibility of its intrinsic origin at the present day. There is much to be said in favor of this view of the etiology of the infectious diseases; but it is opposed by the experimental evidence, which shows that "pure cultures" of known disease germs are as potent in producing the specific morbid phenomena as is material derived directly from the diseased organism.

In the case of anthrax there can be no doubt that this is true, and that living anthrax spores may produce the most virulent form of the disease independently of any non-living material derived from a preceding case. The experiments of Koch seem to have established the same as regards the tubercle bacillus, pure cultures of which are said to produce tuberculosis in rabbits and in guinea-pigs as certainly and as promptly as do inoculations with sputum or other material derived directly from the diseased organism. These experiments have been repeated by Watson Cheyne, of London, with the same result.

I cannot doubt that these gentlemen have obtained the results reported by them from inoculations with pure cultures in the sense that no other micro-organism was present in these cultures. The only possible question is whether these cultures were pure in the sense that they did not contain any remnant of a non-living tubercle virus. How many successive cultures must be made in order to insure this result we cannot definitely determine, but evidently more are required when cultivation is conducted upon the surface of a solid culture medium, than in fluid cultures in which a considerable amount of fluid serves to dilute the non-living material which in the diseased organism is associated with the living microbe. There can be no question, however, that a non-living poison which originated in the diseased organism independently of the parasite would, in the end, be excluded by the method of successive cultures, whether these are made in a fluid or upon a solid substratum. On the other hand, a virus produced by the parasite as a result of its normal physiological processes would be present with it in each successive culture.

It may well be that all of the different pathogenic bacteria produce special poisons to which their specific action is due. But a poison produced by the parasite itself, whether grown in an animal body or in a culture fluid, is evidently secondary as an etiological agent, although it may be an essential factor in giving the parasite pathogenic power. We may suppose that such a poison secreted by the invading micro-organism prepares the soil for its future growth; just as the abnormal growths upon various plants known as galls are supposed to be produced by the irritant action of some poisonous liquid introduced by the sting of an insect, which at the same time deposits an egg. A virus, on the other hand, which was produced in the diseased organism independently of any parasite, but which furnished the soil suitable for the development of a particular microbe, would be the essential etiological agent in the production of the morbid phenomena, and the parasite, if not a mere epiphenomenon without etiological import, would at least be only a secondary factor, capable, perhaps, of doing harm by inducing changes in morbid products, as, for example, the cheesy degeneration of tubercle nodules, and of transporting the virus to new localities and thus giving the disease an infectious character.

As heretofore remarked, this hypothesis must give way before the evidence furnished by pure cultures. And it must be admitted that the experiments of Koch leave very little ground for believing that it is true as regards tuberculosis. It is not safe yet to generalize, however, and it does not follow that it is not true for small-pox and other diseases in which pure cultures of the parasite present in diseased tissues have not been proved to be potent in the perpetuation of the morbid phenomena in other individuals.

We need a non-living poison or virus in order to explain the action of the tubercle bacillus; for I do not feel prepared to admit that the effects which follow inoculations with pure cultures of this microbe are due to mechanical irritation alone. I have recently repeated the experiments of Formad, of Philadelphia, in which he claims to produce tuberculosis by inoculations with finely powdered inorganic material suspended in water. My experiments have satisfied me that, when the material is thoroughly sterilized, and no tubercle bacilli are introduced at the same time, tuberculosis does not result from such inoculations. We know that the lungs of man are very commonly loaded with particles of carbon, and that these angular particles, which are much larger than the tubercle bacillus, do not give rise to the development of miliary nodules. Therefore, I say, we need something more than the bacillus to account for the formation of these nodules, in which the parasite finds a suitable soil for its development.

If tuberculosis was originally of extrinsic origin and is to-day produced by "pure cultures" of the bacillus, there can be no question that this something else is excreted by the parasite, and is consequently ever present with it ready to produce its specific effect when in contact with susceptible animal tissues. Not all vegetable tissues react in the same way to the sting of the various species of gall-insects, and in like manner we have differences in susceptibility to disease poisons among animals of different species, and among different individuals of the same species. The supposition that the different pathogenic organisms give off different kinds of poisonous products as a result of their normal but severally distinct physiological processes, is sustained by what is known of the action of non-pathogenic organisms of the same class in various processes of fermentation and putrefaction, and by the facts which relate to the influence of protective inoculations and the non-recurrence of the specific infectious diseases in the same individual. I have elsewhere discussed this subject (see my work on "Bacteria," p. 246), and cannot at present give my reasons for believing that insusceptibility results from acquired tolerance to the poisonous products evolved by pathogenic organisms, rather than to a change in the system which has rendered the soil unsuited to their development.

The question whether pathogenic bacteria are distinct species having permanent physiological characters upon which their pathogenic power depends, or whether they are varieties of common and usually harmless species which acquire this power temporarily as a result of special conditions relating to their environment, is one of the greatest importance, and one which is at present prominent in the minds of the leading investigators in this field.

Buchner's claim that the anthrax bacillus is simply a variety of the common hay bacillus, and that one may be transformed into the other by special methods of cultivation, has, upon fuller investigation by Koch, Klein, and others, been shown to be without foundation. We now recognize not only that these species have distinct physiological characters of a permanent kind, but also that during certain stages of their development they differ morphologically. Indeed, the specific distinction is sufficiently well marked by morphological characters alone. But it does not follow that there is nowhere in nature a non-pathogenic variety of the anthrax bacillus from which the pathogenic variety known to us has been derived.

So, too, in the case of the tubercle bacillus we are not acquainted with any harmless bacillus having exactly the same form and color reactions, and among known species the bacillus of leprosy is the only one which very closely resembles it. But it must be remembered that we have only just commenced the study of this extensive class of micro-organisms, and that thus far it is the pathogenic species which have received the greatest attention. When we come to know more of the bacterial flora of the exterior world, we may find that all of the species which invade the bodies of animals as harmful parasites are represented by harmless species which cannot be distinguished from them except by the test of inoculating susceptible animals.

In the case of an organism like the anthrax bacillus, which grows readily in a variety of culture fluids, and within comparatively wide temperature limits, it seems altogether probable that the conditions necessary for its growth may be found external to the bodies of animals and outside of our laboratories. But it would be an unwarranted assumption to suppose that its continuous development in this way must necessariiy modify its pathogenic power. For this is retained in full force through any number of successive generations in laboratory experiments, except when the cultures are subjected to the special conditions which have been shown to modify this power, and which, following Pasteur, we speak of as effecting an "attenuation of virulence." The question is whether a similar attenuation may not be effected by natural conditions, and whether the attenuation may not be carried to the vanishing point. This is possible, but we have at present no evidence that it is true.

In the case of the tubercle bacillus, it has been shown that the conditions of development are so restricted as to soil and temperature required that it may be doubted whether these conditions are ever found in nature. It grows slowly upon blood-serum prepared by Koch's method, and not at all unless the temperature is very carefully regulated to about 38° C. Evidently if in a tropical country the temperature were sufficiently elevated and uniform to insure its development, the proper pabulum might be wanting; or if this were present other bacteria which multiply more rapidly would most certainly take possession of it, in the absence of artificial precautions for their exclusion, before the tubercle bacillus had fairly commenced to grow. It seems probable, therefore, that this bacillus, as we know it, has no external habitat, and that it depends for its existence upon the conditions which it finds within the bodies of animals subject to the disease tuberculosis.

But, for reasons already given, we are forced to the conclusion that at some time in the past this bacillus had an external habitat; else we must concede that the disease tuberculosis was originally of intrinsic origin and must relegate Koch's bacillus to a secondary place in its etiology. We have among the higher animal parasites a certain number which have the power to shift for themselves and to bring up a family independently of the host upon which they habitually depend for their sustenance. Others depend entirely upon their host, and students of biology are familiar with the singular modifications which many of these have undergone to fit them for their parasitic existence, and which make it impossible for them to exist independently of the animal which they infest. No doubt is any longer entertained with regard to the fact that the structural anomalies exhibited by these parasites are due to modifications which have been effected gradually, and that useless organs have disappeared and useful ones have attained a special development under the influence of conditions relating to the environment of the parasite and in accordance with the laws of natural selection.

It is probable that the minute vegetable parasites which we know as "disease germs" have in like manner undergone various modifications, if not in form at least in their physiological characters; and it may be that some of them have thus lost the power of independent existence under natural conditions. Others may find the conditions essential to their development both within and without the bodies of animals. Indeed, we know that such is the fact as regards several species which have been shown by laboratory experiments to have the power of inducing infectious and fatal forms of disease in certain animals, and which, nevertheless, exist widely distributed in nature. Koch's bacillus of induced septicæmia in the mouse, the bacillus of malignant œdema, which is much larger and closely resembles the anthrax bacillus, and the micrococcus of induced septicæmia in rabbits, which I have especially studied, are all disease germs of this kind. Their pathogenic power is not a temporary character, but is limited to certain species of animals in the bodies of which they find conditions favorable for their development; and, so far as we know, the infectious diseases which they induce do not arise spontaneously in these animals.

Other disease germs, such as the micrococcus of fowl cholera and that of swine plague, are only known to us because they induce these forms of disease, and the question whether they exist in nature, independently of the animals which they infest, has not been definitely settled. If they do, we should expect to hear of the development of these diseases independently of infection directly traceable to a similarly diseased animal. I am not sufficiently familiar with the evidence to say whether it supports this view of the case or not. But as regards the germ of typhoid fever, which we can scarcely fail to believe in, although there has been no satisfactory scientific demonstration of its existence, and as regards the cholera bacillus —or spirillum—of Koch, which, there is good reason to believe, bears an essential etiological relation to the Asiatic pestilence, there seems to be ample evidence of power of multiplication external to and independently of the human organism. We have known for some time that the germs of these diseases are sown in the discharges of those suffering from them; that certain conditions as to organic pabulum and temperature are necessary for the germination and rapid multiplication of this kind of seed; and that the evidence of such germination and multiplication is found in an abundant harvest of fresh victims.

But do these germs in their external development undergo modifications which cause them to lose or to gain in pathogenic power, and are they ever harmless organisms which may be introduced into the human intestine with impunity? The wide difference in the malignancy of different epidemics and the fact that during the same epidemic the disease may at first assume a mild form and subsequently develop a most malignant character, indicates that the germ, if it be in truth the essential factor in the production of the disease, must undergo modifications of its pathogenic power. And once having admitted the possibility of such modifications, it is hard to place a limit upon them.

There are two infectious diseases of man, one of which has been lately proved to be due to an invasion of the affected tissues by micro-organisms, and the other of which I can scarcely doubt has a similar etiology, which seem to me strongly to support the view that bacteria which are ordinarily harmless may, as a result of special conditions relating to their environment, acquire pathogenic power. These diseases are erysipelas and hospital gangrene. It seems to me beyond question that these diseases may, under certain circumstances, originate *de novo*, that is, without direct or indirect infection from a preceding case. And hospital gangrene especially is so rare a disease that we can hardly suppose that the outbreaks which occasionally occur at widely remote localities are necessarily connected with preceding cases, although these diseases are known to be highly infectious and to cling to infected hospital wards with great tenacity.

I have in mind an outbreak of hospital gangrene which occurred under such circumstances as seem to me to

justify the belief that the epidemic was of local origin. In the summer of 1862 a large number of sick and wounded men from the army of the Potomac were placed upon a transport vessel at Harrison's Landing, Va., and brought directly to Portsmouth Grove, R. I. This location possessed great natural advantages both from a sanitary and from an æsthetic point of view, and, before the arrival of this ship-load of sick and wounded soldiers enjoyed a high reputation for salubrity. A quiet summer hotel, looking out upon the waters of Narraganset Bay, formed the nucleus of the general hospital which was quickly built. Until this was completed the patients were cared for in hospital tents. Soon after the completion of the hospital building I was ordered to Portsmouth Grove, and upon my arrival there was placed in charge of the surgical wards. These were detached frame buildings, made of new lumber and constructed upon the plan which had been adopted for our barrack hospitals, and which is generally conceded to have been excellent. My wards were full of cases of suppurating gunshot wounds. This was before the days of carbolic acid, at a time when we had no positive knowledge of disease germs, and before we had learned to look upon a sponge as an abomination not to be admitted to a surgical ward. My patients were treated in the usual manner with cold-water dressings to recent wounds, and frequently renewed absorbent dressings and ablutions with warm water when suppuration was fairly established and there was no inflammation. I dare say the saucers for giving off chlorine gas, which were in those days supposed to be an important element in maintaining the purity of the atmosphere in the wards of our military hospitals, were duly arranged beneath the several beds. Whether they were or were not, a matter in which my memory does not now serve me, is of small importance; for we now know that it is impossible to disinfect the air of an occupied apartment, and that the presence of chlorine gas or of carbolic acid in respirable amounts has no terrors for disease germs.

Up to a certain point my patients continued to do well, but after a time I recognized the presence of some malign influence in the wards which was counteracting the *vis medicatrix naturæ* upon which I relied for the cure of these gunshot wounds, and which caused wounds that had previously been healing kindly to assume an angry look and to discharge an undue amount of unhealthy pus. Very soon the condition of some of these suppurating wounds became still more alarming. Instead of a simple arrest of the healing process and an unhealthy discharge, I had to deal with a rapidly extending necrosis of the tissues. The most trifling wounds in robust young men which were cicatrizing in a most satisfactory manner, as well as those more serious injuries which had necessarily given rise to protracted suppuration and depression of the vital powers, would suddenly commence to extend by sloughing, and a superficial wound the size of a twenty-five-cent piece was liable within two or three days to become an ugly and deep sloughing ulcer the size of my hand or larger. In a word, I had to deal with that dread disease hospital gangrene. I can hardly doubt that this rapidly developed necrosis of tissue, extending from the wound as a centre, was due to invasion by some micro-organism, and I infer that the pathogenic power exhibited by this hypothetical organism was developed in my wards as a result of exceptional conditions of environment by some omnipresent and usually harmless microbe. Otherwise, how is it that solitary cases of suppurating wounds scattered far and wide over the country never become affected with this disease, which only occurs where numbers of wounded men are massed in hospitals? That the disease was a local one, due to some noxious agent which invaded the wound, and which was transmissible from one to another, and was not due simply to a depressed condition of the general health of those attacked, was evident. This was especially shown by the results attained by vigorous local treatment in connection with the segregation of patients and general measures of disinfection, when by the thorough use of the actual cautery or of fuming nitric acid the entire wound was thoroughly and deeply cauterized, the infectious agent was destroyed, and the *vis medicatrix naturæ* proved sufficient to effect a speedy cicatrization of the deep and broad ulcers which resulted from the rapid sloughing and the heroic treatment required to arrest it. Facts of this kind, taken in connection with circumstances relating to the gradual development of malignancy in local epidemics of other infectious diseases, such as diphtheria and scarlet fever, and the evidence relating to attenuation of pathogenic power in known disease germs, cause me to give more weight to the supposition that this pathogenic power may in certain cases be an acquired physiological character, rather than an inherent and specific one, than is accorded to it by Koch and some other leading investigators in this field. I believe, however, that Koch admits the possibility that his cholera bacillus may be a pathogenic variety of a harmless organism. At least he has submitted the question for discussion.

Klein, of London, also favors the idea that pathogenic power is a specific and constant character belonging to the micro-organisms which exhibit it. We must admit that this is true in the case of such diseases as small-pox and measles, if they are in truth germ diseases, for we have no evidence that these diseases ever originate independently of preceding cases, or that the infectious principle is capable of multiplication external to the human body. But I am very much inclined to believe, for reasons already given, that it is not true as regards the various septic organisms which are known to us by laboratory experiments. I am convinced, however, that there are among these lowly plants a large number of distinct species, each having its own independent life-history, and each subject to modifications of function, and possibly of form, as a result of gradual changes in its environment.

Billroth and some of the earlier observers maintained that the various forms of bacteria which are found in organic infusions belong to a single species of plants—the *coccobacteria septica* of the author named. But this view is no longer tenable. Nor can I agree with Nägeli that there exist but a small number of species, each of which may assume a variety of forms. This author has said: "Each of the veritable species of schizomycetes is not limited to presenting itself under the different forms of *micrococcus*, *bacterium*, *vibrio*, and *spirillum*, but can also show itself as the agent of the acidification of milk, of putrefaction, and as the agent producing several maladies." My own observations have convinced me that there are, for example, numerous species of micrococci, and that micrococci never under any circumstances develop into elongated or spiral bacteria, and do not form endogenous spores, their life-history consisting in multiplication by binary division. I have had in cultivation at different times several different species of these minute plants, and have found that by proper precautions pure cultures may be maintained through successive generations. In other words, that the several species "breed true." Thus the yellow micrococcus—*M. luteus*—produces successive generations of yellow micrococci; and although the individual cocci cannot be distinguished by their form alone from other micrococci having a different color, yet this character being constant is a sufficient specific distinction. The known species of bacilli which may be distinguished from each other by form, dimensions, or physiological reactions, are already sufficiently numerous, and I cannot doubt that the number of unknown species is far greater. Our knowledge of this extensive microscopic flora is still very incomplete, and is obscured by erroneous observations and the confusion which has arisen from the minute size of these microscopic plants and the intermingling of numerous species in the same organic infusions. Methods of isolating and maintaining pure cultures of the several species which

have been devised, and especially Koch's method of surface cultivation, together with improvements in technique and in optical appliances which have been made within the past few years, have, however, opened the way for rapid progress in the future, and we may hope that before many years we will know much more about disease germs than we know to-day, and that the important questions to which I have briefly referred relating to their origin, relationships, and *modus operandi* will finally be settled by the experimental method.

Unless, however, the few individuals in this country who have endeavored to take part in these researches receive more encouragement and substantial assistance from some source in the future than they have received in the past, we shall have the humiliation of still receiving our knowledge of disease germs at second hand, and of knowing that this great nation, which has taken the lead in so many branches of scientific research, has contributed little or nothing to this important subject.

I shall now endeavor to make you familiar with the morphology of a few disease germs, and with that of some harmless organisms of the same class, by projecting upon the screen some of my photographs from nature—photo-micrographs. Should any gentlemen of the press be present, I beg that they will not refer to the objects which they are about to see upon the screen as "bugs," as did an intelligent reporter in New Orleans in giving an account of a lecture illustrated in the same way which I delivered in that city some years since. By the way, the popular idea of a disease germ in the city referred to at the time mentioned seems to have been that it is a bug of some kind; for in the Mardi Gras procession of the same year, an honored member and vice-president of this association, whose death we were soon after called upon to mourn, made his appearance in *papier-maché* upon one of the flats, as engaged in fishing for germs. In his hands was a slender fishing-rod furnished with a hook and line, and from the hook dangled a nondescript creature which represented a recently captured germ, and which resembled a Louisiana mosquito more than anything else; perhaps this was the most pestiferous creature with which the inventor of this tableau was acquainted. At that time a "germ-hunter" was thought by many good citizens, and by not a few of our own profession, to be a crank who deserved no encouragement, and was a fair subject for the shafts of ridicule and scorn. But the world moves, and many of these honest citizens, including some of the then scornful members of our own profession, are now prepared to swallow germs served up in any style, so long as they are imported. And, indeed, they may, in my opinion, swallow with impunity some of these imported germs, as for example the *bacillus malariæ* of Klebs and Tomassi-Crudeli, or the yellow fever germ of Domingos Freiré, of Brazil.

Although I object to my disease germs being called bugs, I cannot find fault with another gentleman of the press, who, on a different occasion, gave his impressions of the morphology of the objects which he had seen upon the screen by telling the readers of the journal which he represented that some of these objects looked like Bologna sausages and some like oysters on the half shell. You will at once recognize the Bologna sausages when the photo-micrograph of a chain consisting of four bacilli is projected upon the screen, but I am still in doubt which of my photographs from nature suggested oysters on the half shell.

State Medical Examiners in Pennsylvania.—At a stated meeting of the Philadelphia County Medical Society, held October 1st, resolutions approving of the appointment of a State Board of Examiners, and directing the appointment of a committee to draft a law for the creation of such a Board, were unanimously adopted.

M. Charcot has been elected a member of the French Academy of Sciences, in place of the late Baron Cloquet.

NASO-PHARYNGEAL FIBRO-SARCOMA REMOVED WITH GALVANO-CAUTERY ÉCRASEUR.[1]

By R. P. LINCOLN, M.D.,

NEW YORK.

The specimen I present to the Society to-night, I removed, July 22d, from a boy sixteen years of age. The history of the case is in brief as follows: The patient is of Irish parentage, never very strong and always a sufferer from nasal catarrh. He first noticed obstruction to nasal respiration in the autumn of 1881. At that time, and ever since, he has had frequent hemorrhages, the blood flowing first from the right nostril, but soon from both nostrils and the mouth. The quantity must have been considerable, for he described it as at times amounting to bowlfuls.

It was usually excited by active exercise, as running; latterly stooping would start it. Sometimes he would be awakened at night by a hemorrhage.

In the spring of 1882 the right nostril was stopped up, and within a year of this time both were occluded. About a year ago the tumor appeared to view at the margin of the right nostril, and at about the same time it could be seen in the pharynx when the mouth was opened.

In November, 1882, an attempt was made to remove the tumor by means of ordinary polypus-forceps, but was abandoned without accomplishing the desired result. I first saw saw the patient July 12, when he was referred to me by Dr. Satterthwaite. At that time there was a slight but noticeable fulness of the right side of the nose. The right nostril was filled to its margin with a growth covered with mucous membrane of a pink color. The septum nasi was crowded well over to the left. On examining through the mouth, the soft palate was seen deflected to a perpendicular, extending a little below its border, and filling the post-nasal space and pharynx was a tumor of the same appearance as that in the nostril, but with its inferior pear-shaped base rough and ulcerated in spots.

A further examination proved that the two presenting masses were parts of the same tumor, and attached to the vault of the pharynx and roof of the right nostril with a large pedicle and extensive attachment. As the growth was very large, exceedingly vascular, and evidently growing rapidly, I advised an immediate operation with the galvano-cautery écraseur, without the preliminary treatment by electrolysis, which I have heretofore practised in similar cases treated and reported by me. I also insisted that subsequently the stump should be thoroughly destroyed by means of the galvano-cautery. Other reasons that influenced me in deciding to operate at once was, that I had prepared to leave the city till September, and I feared that a delay till my return would find the patient still more reduced physically than at this time. Moreover, a fatal termination was liable to happen.

July 22d.—With the kind assistance of Drs. Satterthwaite, Goodwillie, and McCarroll, I proceeded to operate, at the hospital of the New York Post-Graduate Medical School, in the following manner: The patient having been anæsthetized I passed along the floor of the right nostril a looped platinum wire, protected by a double canula, the two parts of which could be disengaged from each other without removal, for the greater facility of carrying the wire around the base of the tumor. The loop being brought to the margin of the palate, was drawn backward, opened, and carried below and behind the pendulous portion of the tumor up to its attachment at the base of the skull. This was accomplished by the conjoined manipulation of the fingers of one hand, while the two parts of the canula, now separated, were operated by the other hand, and at the same time withdrawn, leaving the wire surrounding the pedicle at its base. The terminals of the wire were next passed through the

[1] Presented at the New York Pathological Society, October 8, 1884.

leader of the galvano-cautery handle, and having been tightened and connected to the battery, the pedicle was slowly cut through without hemorrhage. The tumor was then withdrawn through the mouth. It measured in its greatest length four inches, and two and a half in thickness, the latter being the portion that extended into the pharynx, while the former was the part that protruded into the nostril. The cauterized surface measured two inches by one and three-fourths. Its weight, five days after the operation, was two ounces and three-fourths. Its freshly cut surface presented a bluish-white fibrous appearance, mottled here and there with a purple color marking the seat of interstitial hemorrhages.

Dr. George R. Elliott kindly made a microscopic examination of the tumor and pronounced it a fibro-sarcoma.

On account of the interest attached to this case, I will quote in full Dr. Elliott's report.

"There are round and spindle cells, having large granular nuclei; there are also branching cells distributed throughout the entire mass, and in places these cells are aggregated together. In many portions of the tumor true fibrillated tissue is present. The above tissue elements are present in the following order as regards bulk: First, fibrous tissue; second, sarcomatous tissue (round and spindle cells); third, myxomatous tissue (round and spindle cells). The tumor is quite vascular, and numerous sites of hemorrhage, old and recent, exist. In the fibrous portions the walls of the blood-vessels are greatly thickened. In the truly cellular portions of the growth the vessels have no distinct walls, and appear to be mere vascular channels running throughout the cellular substance."

A week after the operation I examined the patient at my office, and found the cut surface well cleared off and presenting an apparently healthy wound, and appointed the 1st of September to apply the galvano-cautery to the seat of the growth, so as to completely destroy all abnormal tissue. This practice I believe is essential to prevent a recurrence of the growth. The patient neglected to keep the appointment and I did not see him till September 17th, when I found the wound entirely healed and presenting a healthy appearance, except a small portion of the cicatrix near the posterior entrance to the right nostril, where there appeared to be more vascularity and a little more prominence than the surface in general exhibited. I was anxious to carry out my plan of treatment without delay, and appointed the following day for that purpose, but I have not yet been able to secure the co-operation of the patient.

To Facilitate the Passage of the Catheter when the Deeper Portion of the Urethra is Especially Sensitive.—Dr. Andrew H. Smith, of New York, sends us the following practical hint: "In the absence of actual stricture an undue sensitiveness of the membranous portion of the urethra often causes pain and spasm the moment the catheter reaches that portion of the canal. As the operation is usually performed, the difficulty is increased by the fact that the back of the instrument reaches the sensitive portion of the canal in a dry condition, that is to say, the oil or other lubricating substance with which it was smeared, has been wiped off by contact with the walls of the urethra before the point is reached at which a lubricant is most needed. This difficulty can easily be overcome in the following manner: Immerse the catheter in oil, in such a way that the oil will fill the lower third of the instrument. Then close the upper end with the finger, and keep it closed until the back of the catheter reaches the sensitive spot. Then remove the finger and allow the oil to flow out of the eye of the instrument and bathe the surface of the membrane. If, at the same moment, the catheter is carried gently onward, it will often enter the bladder as easily as it has passed the wider portion of the urethra."

A UNIQUE GLASS WOUND.

Successful Ligation of the Left Common Carotid Artery and Internal Jugular Vein.

By R. M. STONE, A.M., M.D.,
OMAHA, NEB.

At noon, on May 8, 1884, Melvin S——, aged twenty-four, while assisting in the removal of a plate glass 4 feet by 8 feet, was precipitated into the cellar, the glass following, and of course being broken in its descent. S—— jumped to his feet unaware that he was injured, but in the next instant saw a stream of blood shooting up from beneath his left ear. He recognized at once that his jugular vein was cut and that he must have assistance within a very few moments or perish.

A few days before this occurrence his father and he had been discussing the question of what to do for a person bleeding from a wound; Melvin then had said that should he see such a case he should jam his thumbs deep into the wound and try and hold the vessels till help came. So with rare presence of mind he jerked off his glove, pressed the ball of his left thumb hard against his neck below the wound, and ran south some thirty or forty feet to the cellar stairs, then north across the street to the nearest physician's office, not less than three hundred feet from where he fell. He ran so rapidly that his father chasing him could not catch him. Melvin rushed into the open office, saw no one present, wildly tried the inner doors in the vain hope that Dr. Swetnam was within, exclaiming, "O Doctor, why are you not here?" and again staggered on to the pavement. I happened to be standing in front of my office, quite near, and saw a friend across the street frantically gesticulating and beckoning me toward the corner. I ran and soon saw Melvin staggering, bleeding, and gasping, a terrible torrent of arterial and venous blood pouring side by side from his neck. I thrust my thumb deep down into the vast opening and with my elbows turned him on to his side on the door-step. By pressure with my right thumb on the vessels from below, with my left against the base of the skull being able to feel plainly the styloid process, I was able to check the flow almost entirely. I sent for assistance and in a very short time had the gratification of seeing Drs. M. A. Rebert, E. W. Lee, and Geo. B. Ayres at my side. No surgeon was ever more happy at the sight of a silk thread than I, when I saw Dr. Lee coming running with one in his hand. By this time Melvin was almost gone, his face deathly white, eyes rolled upward, jaw dropped, and he was gasping and struggling for his apparently last breath. We all had the one thought that he could not live long enough to permit ligation.

The position of the wound beneath the ear showed that the arterial blood must come from the carotid; the depth of the wound, which admitted my left thumb over two inches, the fact that I could feel the styloid process and beyond it, made it probable that the venous blood came from both jugulars. The frightful loss of blood, the certainty that the patient would die before the severed external carotid could be caught in the wound and ligated, the possibility that the internal carotid was either severed or injured made it necessary to tie the common carotid; this and the internal jugular vein were then ligated above the omohyoid by Geo. B. Ayers, M.D.

Meanwhile Dr. Rebert had taken my place, and thrust his thumbs into the wound. After the ligation of the carotid, he also observed that his thumb went beyond the styloid process and apparently to or near the jugular foramen, and the slightest removal of the thumb from the base of the skull allowed a seemingly undiminished stream of blood to pour forth.

We felt that our patient was too near death to allow us to search for the distal ends and ligate, and that a compress soaked in dilute Monsell's solution was our only resource. A pledget of cotton, followed by layers of sheet-lint, were quickly placed in position and the hemorrhage was completely arrested. Several other face and

scalp wounds were sewn up while awaiting a vehicle to carry Melvin home.

The operation had taken place, fortunately, in the open air, with the best of light and air, except as interfered with at times by the anxious hundreds who stood watching.

The father had sat holding his son's hand during the trying ordeal, and Melvin had gone through with it most bravely, answering once or twice as we spoke, fearing he was dead, "All right yet, father, hold my hand." He told me afterward that the operation gave him no pain, that the condition following the loss of blood was that of anæsthesia. A stimulant had been given and the pulse, which was at times very feeble and almost imperceptible, became fuller and stronger, and he bore the ride home remarkably well. Melvin had shown so much pluck, judgment, and vitality that, though we dared not think he had a ghost of a chance for final recovery, we could not help the thought that if any one could recover from such an injury he was the one.

Though our patient had passed safely through one of the greatest dangers that ever befell a man, yet we knew, and he soon learned it too, that he must face the other dangers of secondary hemorrhage and pyæmia, none the less to be feared.

Melvin rallied within two hours, by the aid of hot bottles, became warm, and had a fair pulse of 76. He received quinia, gr. iij., and morph., gr. one-eighth, every two hours; and whiskey, ℥ j., and a glass of milk every hour. We crowded the milk to the amount of a gallon a day, so as to make up as rapidly as possible the loss of blood. By 7 P.M. reaction had well taken place, the heart's action was strong, his voice clear and strong, the milk had been assimilated and we suspended the drugs mentioned and gave fl. ext. ergot, ℥xv.; sodium bromide, gr. xv., every three hours instead. We continued these drugs for their action on the circulation at increasing intervals for four days, suspending them as we saw indication of beginning strangury, caused by the ergot, which ceased very soon upon its withdrawal. I have a very frequent record of the pulse and temperature up to convalescence, but it would only be tedious to insert it; suffice it to say that his morning temperature was between 99½° and 100°, uniformly for twenty days, and his pulse between 70 and 80; his evening temperature was between 100½° and 101°, uniformly for twelve days, except on one occasion, the night of the seventh day, when it reached 101¾°, while his evening pulse was 82 to 84 usually, rising to 96 and 100 on three occasions only.

Besides the medicines mentioned I gave our patient from five to ten grains of quinia, with an equal amount of lactopeptine, daily during the first two weeks, except on the night of highest temperature, when we gave fifteen grains. I gave him one-eighth grain of morphia twice or thrice daily by the mouth for three days, and, after that, from one-eighth to one-fourth grain hypodermatically from thrice to once daily during the next fifteen days.

The margins of the compress were kept sprinkled with Wyeth's finely powdered boracic acid until pus began to flow from beneath, when the compress and margins were thoroughly and almost constantly irrigated with a solution of the bichloride of mercury 1 to 2,000 or 1 to 4,000. While irrigation was not going on and during sleep a piece of sheet-lint, previously soaked in the same solution, was laid over the wound. Hunyadi Janos water was used internally, and rectal injections of warm water with glycerine and ox-gall added to counteract the constipation caused by a milk diet.

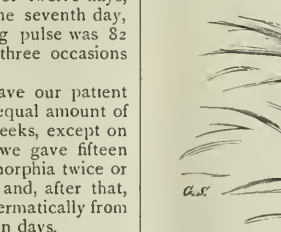
Our patient's stomach remained in excellent condition during the whole time; he drank and assimilated large quantities of milk and two egg-nogs, with a little sherry or port wine in, daily. Owing to the head bandage over the compress his position was necessarily a constrained one, and yet he rested well every night and was delirious but a few times, and only then on waking; he suffered from headache on the third and fourth days only.

During the ten days following the accident I watched most anxiously and often at the bedside, dreading the appearance of secondary hemorrhage, and had the pleasure of seeing this dangerous period pass without the slightest trouble from this source, or the other of pyæmia.

On the third day there was pus at the wound of ligation, but no moisture whatever at the margins of the compress. On the sixth day I had the pleasure of a visit from my venerable friend, Dr. Louis Bauer, Dean of the St. Louis, Mo., College of Physicians and Surgeons, and we were all very glad of the privilege of his counsel. His views as to the necessity of then cutting the bandage over the compress, loosening thus the irksome pressure, and the very gradual removal day by day of the layers of the lint compress coincided with our own, and this was done. He assured us that the plug in the ends of the vessels must be well organized, and we had nothing to fear in the very cautious removal of the compress. On the seventh day pus began to flow quite freely from beneath the compress, and from this time on the bichloride solution was most assiduously used; on this day occurred the only notable rise of temperature, and I greatly feared that pyæmia had indeed begun; the temperature and pulse, however, quickly fell, the delirium subsided, and we had no further cause for uneasiness.

Little by little I had removed the layers of the compress, which allowed better irrigation, and on May 17th there remained but the pledget of cotton, loose, easily moved, and adherent in a few spots only. Melvin had now passed nine full days, had no fear whatever of secondary hemorrhage, was jovial and happy, and kept asking for a cigar.

On May 23d, the fifteenth day, the cotton pledget came away; though a very little traction could have removed it at any time since May 17th it was deemed best not to remove it and thereby possibly endanger the integrity of the clots in the mouths of the vessels. We now could see the full size of the cavern, though granulation had been going on for some days; it was, by careful measurement, 1⅜ inch in depth and 2½ inches wide at the surface, tapering to ½ or ¾ inch in width at the bottom: on the front wall of the cavern, near the bottom, could be seen and felt the styloid process. On May 25th a photograph was taken, from which the accompanying



woodcut was made. The walls of the cavern were lined with the most beautiful and healthy granulations, which, under the irrigations, remained so and very rapidly filled the cavity. On June 5th the cavity was reduced to three-fourths of an inch in depth and width, and on June 27th a fine probe could hardly be inserted in the cavity, and only a slightly more deep than normal depression existed beneath the ear. We had expected a salivary fistula to remain, since the parotid gland was laid wide open, but it did not.

On June 12th, the thirty-sixth day, I removed one of the ligatures. The other, which had previously resisted quite strong traction, was removed on the seventy-ninth day.

On June 24th Melvin was able to come down town and receive the congratulations of the many friends who had often enquired about his condition.

What condition now existed? The facial nerve having been severed, our patient is unable to frown with the

left side of his forehead, cannot close his left eye, has no motion of the muscles of the left cheek, his tongue points far to the left when protruded, the left angle of his mouth is one-half or three-fourths of an inch beneath the right, and he is one of the few unfortunate individuals who literally laugh out of one corner of their mouths. He has suffered considerable inconvenience from his exposed cornea; lachrymation has been profuse two or three times from irritation, and this will no doubt prove the most serious source of trouble. He is acquiring the habit of brushing the cornea with his upper lid, and hopes in this way to get along, but I fear that it will not answer, and sloughing of the cornea may result.

There are a few features of the case that are unusual, and I think worthy of special mention. Superficial glass wounds are numerous, and wounds involving the radial and ulnar arteries and the palmar arches are quite so, but I cannot find recorded a case of a wound of the carotid region made by glass. This was also one of the rare cases where distal ligation was absolutely out of the question; any attempt in that direction would certainly have been fatal, and no surgeon of good judgment would for a moment have thought of it.

But the most interesting and unique feature about the case seems to me to be that the internal jugular vein was probably shaved off close to its emergence from the jugular foramen, and if so, rendered distal ligation absolutely impossible. An autopsy alone could demonstrate this to have been the fact; but the great depth of the wound, the fact that after ligation of the carotid the slightest removal of the thumb from, at, or very near the foramen, was followed by a terrible welling up of venous blood, incline us to believe that this was the case. I can find but one similar case on record, that of Kochers, found in the "International Encyclopedia of Surgery," vol. iii., p. 504. He had a case of a stab between the fifth and sixth cervical vertebræ. He says that he removed clots and seized "the bleeding point with long forceps, but it was impossible to tie any vessel as the ligature had nothing to grip."

Whatever was the case as regards this point, I trust the history will prove of interest and value, and worthy of record.

CEREBRAL LOCALIZATION—THE CENTRES FOR VISION.

By PHILIP ZENNER, A.M., M.D.,

CINCINNATI, O.

(Continued from p. 345.)

In the three preceding papers we have given the data from which we concluded that a limited area of the cortex in the posterior part of the hemispheres is in close relation with the retinæ, this area, therefore, possessing visual functions. We wish now to map out, as nearly as may be, the more precise relationship of the visual area to the retinæ in man, and to consider some other questions, which deal more closely with the exact functions of the cortical centres.

Relation of optic tracts to retinæ.—We must premise the consideration of relationship of cortex and retina by that of the optic tracts to the retinæ, for, as will subsequently appear, the optic tract is, probably, only in relationship with the hemisphere of the same side, and, therefore, knowing its relationship to the retinæ, we will already have acquired knowledge on the final question—the relation of cortical centre and retina.

In quite a number of instances after destruction of one eye, and atrophy of the corresponding optic nerve, atrophy of fibres in both optic tracts was observed. This atrophy in the optic tracts, always involving only a part of each, is usually determined with some difficulty, and there is consequently some variance in the reports of the extent to which each tract degenerates. Mauthner,[1] after carefully examining all the reported cases, concludes that the larger number of fibres of each optic nerve cross over to the opposite optic tract, while a smaller number of fibres enter the tract of the same side, the proportion of crossed to uncrossed fibres being as three to two.

A number of cases have been reported where hemianopia followed lesions of an optic tract. In most of them the entire tract was not destroyed or there were other complications, so that they can not be utilized for our present purpose. But in one instance, a case of Gowers,[1] there was complete degeneration of one optic tract without involvement of any other important part, so that the case answers our purpose admirably. In this case, according to Gowers' report, there was "a blindness in the symmetrical halves of both fields of vision, which reached in each one to the median line."

There is an apparent discrepancy between the clinical manifestations in Gowers' case, where blindness reaches to the median line, and the pathological observations that more fibres of the optic nerve pass into the opposite optic tract than into that one of the same side. But this discrepancy is only apparent. For a vertical line passing through the point of fixation does not divide the retina into two equal halves. The nasal segment is larger than the temporal, and therefore receives a larger number of fibres from the optic nerve.

Relation of visual area to retinæ.—What has already been learned of the relations of visual areas and retinæ in the lower animals, as well as the relationship of optic nerves and tracts just mentioned, naturally lead us to expect that in man the visual area of each hemisphere is in relation with one half of each eye. Observations in animals lead to this belief, because we find that the higher the animal the more nearly each hemisphere is in equal relation with both retinæ. Thus, in rabbits one visual area is almost alone related to the opposite eye. In dogs about one-third of the visual area is devoted to the eye of the same side; while in monkeys, according to Munk, each visual area is devoted to one-half of both eyes.

The direct observations in man seem to justify this expectation. Of Baumgartner's case it is expressly stated that the hemianopia reached to the point of fixation. Of Curschman's, Marchand's, and Westphal's cases it was said that there was complete hemianopia. In other instances, as cases of Nothnagel, Wernicke, and Stenger, the hemianopia did not reach to the point of fixation and the loss of the field of vision was more extensive in one eye than in the other. But in the latter instances the visual area of one hemisphere was, apparently, not altogether destroyed. So that we may safely conclude from the above cases that each area is in relation with one-half, or almost one-half[2] of both retinæ.

One of the cases given in the previous paper, that of Nieden, seems to throw light on the more exact relationship of visual areas and retinæ, and to point to the existence of the same relationship in man as Munk had observed in dogs, that is, that the external portion of the visual area of one hemisphere is in relation with the temporal half of the retina of the same side, while the median portion of the visual area is in relation with the nasal half of the opposite retina. For in Nieden's patient the original injury apparently involved but a small part of the occipital lobe, that nearest the longitudinal fissure, and there was at that time paralysis of the nasal portion of the opposite retina. At a later period, when probably the process of cicatrization had produced some changes in the part of the occipital lobe lying more externally, there was also paralysis of a part of the temporal segment of the retina on the same side.

Single vision with double retinal images.—Wernicke,[3] taking as a basis that each visual area is devoted to the corresponding halves of both retinæ, and that the more

[1] Gehirn und Auge, p. 427.

[1] Centralblatt f. d. Med. Wissenschaften, 1878, No. 31.

[2] The reason for thus modifying the statement will appear later.

[3] Gehirnkrankheiten, vol. i., p. 236.

proximate relationship in man is the same as Munk had found it to be in dogs, has thus explained the existence of single vision with double retinal images. The explanation is so beautiful, and, withal, so simple and natural, that it, in itself, tempts us to accept as true the premises upon which it is based.

According to these premises the median half of the right visual area is devoted to the median or nasal half of the left retina, while the temporal half of the right visual area is devoted to the temporal half of the right retina; and in each instance the segment of the visual area is so related to the segment of the retina that the central part of the latter is related to the central part of the visual area, its peripheral parts to the peripheral parts of the latter.

This relationship, as well as the projection of the retinal images upon the visual areas, will become more perspicuous by attention to the accompanying diagram: *o p* represents the right, *m n* the left retina; *N P* the right, *m o* the left visual area; *c* the macula lutea. *c n*, the nasal half of left retina, is projected upon *C N*, the median half of right visual area, while *c m* is projected upon *C M*, *c* being projected upon *C*, and *m* and *n* upon *M* and *N* respectively. As *c*, the most sensitive part of the retina, is projected upon *C*, the central part of visual area, the latter is the most sensitive part of the visual area.

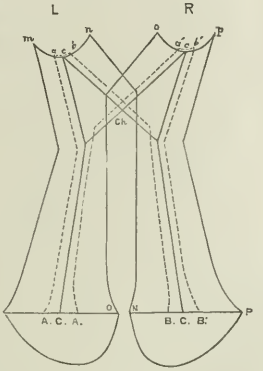


Diagram of the Projective of Retinal Images on the Visual Areas.

a c b and *a' c b'* represent the two retinal images of an observed object. The corresponding half of each image will be projected upon one visual area. Thus *c b* and *c b'* are projected upon *C B* and *C B'*, the central part of the image being projected upon the centre of the visual area, its peripheral parts in the more peripheral parts of the visual area, each point being there doubly represented on each side of, and probably at equal distances from the centre. This double representation appears in consciousness as one, because the corresponding parts are very intimately bound together by associating fibres.

Crossed amblyopia with cerebral lesions.—The above conclusions are not altogether in accordance with the views of two eminent men, both strenuous adherents of the present theories of cerebral localization, Charcot and Ferrier. I refer to the clinical observations of the one, and the physiological experiments of the other. Their observations and results deserve careful attention, because opposing views in such high quarters are likely to throw doubt on the whole subject of localization.

From clinical observations in some cases of hemianæsthesia and amblyopia in one eye Charcot concluded that certain lesions of the internal capsule caused blindness in the opposite eye. Accepting the semidecussation of the optic nerves in the chiasma, he now constructed a new scheme of the cause and final distribution of the optic nerves. According to this scheme those fibres of the optic nerve which do not cross over at the chiasm, but pass into the optic tract of the same side, do cross over and enter into the other side of the brain at some point beyond the corpora quadrigemina. He thus explained that, while lesions of one optic tract would produce hemianopia, lesions of the internal capsule produced a crossed amblyopia.

When it became subsequently known that lesions of the cortex of one hemisphere caused homonymous lateral hemianopia, this scheme being insufficient to explain such conditions, Grasset[1] modified it by a third crossing of the optic nerve-fibres at a point beyond the internal capsule.

The original scheme of Charcot already appeared sufficiently unnatural to cast doubt upon its correctness, but that of Grasset is so very artificial as to rob it of all credence.

In this difficulty we are led to inquire whether Charcot's premises, in the first instance, were correct, whether it is true that lesions in the posterior part of the internal capsule cause blindness in the opposite eye, and that, therefore, all the fibres of one optic nerve pass through the opposite internal capsule.

Many of Charcot's observations were on hysterical cases. These we may altogether ignore, both because the seat of the trouble is unknown and because, in these instances, the visual disturbances are not always of the same character.

Of the cases in which there were cerebral lesions, in some the diagnosis crossed amblyopia doubtless rested upon erroneous observations. In the previous paper we called attention to the fact that it is common for those suffering with hemianopia to state and to believe that they are blind in one eye. They are often much surprised to learn, after a careful examination has been made, that both eyes are alike affected. But there are other cases to which these objections do not apply and which must therefore be examined more carefully.

The first two cases of this kind, with post-mortem results, were reported by Türck.[2] But, inasmuch as there was no evidence that a careful examination of vision was made, these cases may be passed by. In Bernhardt's[3] case there was, with right hemianæsthesia complete blindness in the right eye, but there was, at the same time, concentric narrowing of the field of vision in the left eye.

A patient of Pitres[4] had left hemianæsthesia and hemiplegia and amblyopia in the left eye. But in this case there was also defective vision in the right eye. In both eyes there was concentric contraction of the field of vision. There was also discoloration of both optic nerves.

So in these two cases where post-mortem examination was made (the same seems to be true in similar instances without post-mortem results, whenever careful examination was made) there was not only a crossed amblyopia but also impairment of vision in the eye of the same side; so that these cases do not sustain the original statements of Charcot, or support his scheme of the course of the optic nerve-fibres.

There is only one case, so far as I know, which directly supports this scheme, that is one reported by Mueller.[5] In this case a small lesion was found in the posterior part of the left internal capsule, and, during life, there was on the right side slight paralysis and complete anæsthesia, loss of taste, smell, and hearing in the same side and amblyopia in the right eye. It was expressly stated that vision in the left eye was normal, there being no narrowing of the field of vision.

Wernicke,[6] in reviewing this case, states that the reporter was evidently influenced by Charcot's previous writings, and does not hesitate to pronounce the description of the visual disturbances to be due to faulty observations. This appears to be a very summary way of disposing of what are, apparently, carefully recorded observations, but yet it is not altogether unjustifiable. Charcot has acknowledged that his first observations were incorrect, that visual disturbances could always be detected in the other eye, and the same have been the observations of others in similar instances. But of much

more consequence is the fact that a number of cases have been reported, where, while the post-mortem examination revealed destruction of the posterior part of the internal capsule, visual disturbances of the kind just mentioned (crossed amblyopia) were not found. Such are the cases of Prevost,[1] Pooley,[2] Dreschfeld,[3] Senator and Wernicke,[4] and Vetter.[5] In all of these cases there was hemianæsthesia on the opposite side.

In addition to the above there are other cases of hemianæsthesia where the description of the autopsy leaves us in doubt whether the internal capsule was injured; and others where the symptoms lead us to believe that there was a lesion of the internal capsule; in all of which there was no crossed amblyopia.

These instances are quite sufficient to satisfy us that lesions of the internal capsule which cause loss of general sensation in one half of the body, and may also affect all the special senses, do not directly produce crossed amblyopia, and that Charcot's scheme is not correct. But nevertheless it must be put down as a singular fact that lesions in the neighborhood of the internal capsule should frequently be accompanied by visual disturbances chiefly in the opposite eye. Nothing that has been above said explains their occurrence, but it is to be hoped that this obscure point may be cleared up by careful observations in the future.

Experiments of Ferrier.—We must now speak of the experiments of Ferrier. They are mentioned here, instead of with the other physiological data, because he has recently[6] attempted to bring them into accordance with the above teaching of Charcot.

Ferrier's experiments were made on monkeys; his conclusions (only those relating to vision are here mentioned) are the following:[7] 1. Destruction or bodily removal of one or both occipital lobes almost to the parieto-occipital fissure produces no discernible disturbance of vision. 2. Complete destruction of one angular gyrus produces blindness in the opposite eye, which is of only a few hours' duration. If after a few weeks the second angular gyrus is destroyed, there is only very slight or transient visual disturbance. But if both angular gyri are destroyed at the same time, there is total blindness in both eyes of a few days' duration. 3. Destruction of the occipital lobe and angular gyrus on one side produces homonymous lateral hemianopia. But after a week or more there are evidences of vision on both sides. 4. Destruction of both occipital lobes and both angular gyri causes total and, apparently, permanent blindness, but the presence of one angular gyrus or one occipital lobe is sufficient for vision in both eyes.

Ferrier supposes that each angular gyrus is connected with the central portion of both retinæ, while each occipital lobe is in relation with the corresponding halves of both retinæ. He believes that crossed amblyopia attends lesions of the internal capsule, because, in such instances, those fibres are destroyed which pass from the angular gyrus to the opposite eye. How unsatisfactory as well as arbitrary are these conclusions it is scarcely necessary to mention.

The above experimental results are very puzzling, and seem to be altogether at variance with what we have been taught by other physiologists, as well as with what we have learned from pathological observations on man, for instance, his observation that destruction of an entire visual area produces only transient disturbance, and clinical observations of permanent hemianopia following destruction of one visual area. It seems much easier to believe that the apparent disappearance of visual disturbances in Ferrier's monkeys was due to parts of the visual area (gray matter of the sulci, on the median surface of the brain, etc.) being retained, and to the extreme alertness and sagacity of those animals.

[1] Wilbrand: Ueber Hemianopsie, p. 133. [2] Archiv. f. Ophth., vol. v., p. 148. [3] Brain, vol. iv., p. 543. [4] Gehirnkrankheiten, vol. ii., p. 70. [5] Deut. Achiv. f. Klin. Med., 1883, p. 507. [6] Brain, vol. iii., p. 467. [7] Ibid., p. 420.

There are two of Ferrier's statements which cannot be so summarily treated, and which will, perhaps, require future and more careful observations for a positive answer; these are, that the visual areas include more than the occipital lobes (also the angular gyri), and that each visual area is in relation with the central part of both retinæ.

Luciani and Tamburini[1] also include the angular gyrus in the visual area, but, like Munk, they believe each visual area to be in relation with only one-half of both retinæ. Munk[2] attributes the visual disturbances obtained by these experimenters after destruction of the angular gyrus to direct involvement of the optic radiations, which, according to Wernicke, pass immediately beneath the angular gyrus.

Observations on man do not oppose Ferrier's views, for the disease in all instances was too extensive to say that the symptoms were produced by involvement of the occipital lobe alone.

The second proposition already noted, that each visual area is in relation with the central part of both retinæ, seems to find some support in clinical observations. We have mentioned above the clinical observations which led us to conclude that each visual area is in relation with one-half or almost one-half of both retinæ. The statement was thus modified for several reasons. Though several cases are recorded where the hemianopia reached to the point of fixation, such observations should be received in a guarded manner, for it is very difficult to mark out the exact limits of vision. In a case of right hemianopia, reported by myself,[3] a skilful specialist stated that the hemianopia reached to the point of fixation, though in several very careful examinations made by myself, with the assistance of a medical friend, a very slight curving of the dividing line toward the affected side was positively determined. Besides, there are a number of cases with lesions of the occipital lobe where the hemianopia did not reach to the point of fixation. In one of them, that of Hosch,[4] apparently the whole of one visual area was destroyed. In others, it is true, an entire visual area did not appear to be destroyed, so that we might thus account for the visual defect on one side not being complete. Yet it is a striking fact that, in such instances, just the central part of the field was retained.

The Legal Enforcement of Study at Home.—A novel suit, involving health questions, has recently been decided in one of the English Appellate Courts. A teacher in one of the public schools prescribed certain lessons which were to be learned at home, and when these were not satisfactorily committed to memory a difficulty arose between the teacher and scholar, which is not fully detailed, but which gave rise to the charge of assault and battery against the teacher. The determination of the charge of assault does not appear, but the court where the case was originally tried, and the Appellate Court, both decided that "home lessons set by teachers cannot be enforced." This decision seems to hold that scholars cannot be held responsible for the learning of lessons at any other place than the school-room. It can hardly prevent, however, teachers from giving lessons of such length as to require study out of school hours, and if they are not learned the scholar's standing will necessarily be lowered. Such a result will, of course, modify largely the practical results of the decision. The attention of parents and teachers, here, as well as in England, cannot be too emphatically called to the question whether the requirements of home study, directly or indirectly made, are not in general too exacting for the proper development of the health of children.

HYDROCHLORATE OF COCAINE—EXPERIMENTS AND APPLICATION.

By H. KNAPP, M.D.,

PROFESSOR OF OPHTHALMOLOGY, MEDICAL DEPARTMENT UNIVERSITY OF THE CITY OF NEW YORK.

As soon as I had read the very remarkable communication on cocaine, by Dr. H. D. Noyes, in THE MEDICAL RECORD, October 11, 1884, p. 417, I procured specimens of the new remedy from different sources—Mr. F. W. Foucar, New York; Dr. E. R. Squibb, Brooklyn; and Messrs. Eimer & Amend, New York—and tried its action on myself, some members of my family, and a number of patients. Since that time some short communications on the same remedy have appeared by Drs. C. R. Agnew, W. O. Moore, and J. L. Minor (THE MEDICAL RECORD, October 18, 1884, pp. 438, 439). My observations substantially confirm the statements of these gentlemen. The novelty and importance of the subject may excuse the hasty publication of some experiments and observations which I will describe without much comment as they have suggested and presented themselves to me. As only Dr. Moore mentions something about the substance itself, I looked up, in the desire for further information, some books on pharmaceutical chemistry. The works which I have consulted are: "The U. S. Dispensatory," thirteenth edition, 1870, p. 1591; the same, fifteenth edition, 1883, pp. 563–565; and through the kindness of Messrs. Eimer & Amend, Fehling's "Handwörterbuch der Chemie," 1875, vol. ii., pp. 752, 753, and Hager's "Handbuch der Pharmaceutischen Praxis," 1876, First Part, pp. 903–905. From these books I extract the following pharmacological notes, which may not be without interest.

Cocaine is the alkaloid of the leaves of erythroxylon coca (Lamarck), a shrub growing wild and extensively cultivated in South America, especially in Peru and Bolivia. The leaves resemble those of Chinese tea, and their action is similar to that of tea and coffee. The alkaloid was first isolated from them in 1855 by Gardeke, who gave it the name erythroxyline; but Dr. A. Niemann, of Goslar, Germany, was the first to thoroughly investigate the leaves in 1860. He gave the alkaloid the name cocaine. Lossen, who followed in his footsteps, analyzed it and expressed its composition by the following formula: $C_{17}H_{21}NO_4$. "It acts upon the lower animals much as does theine. It tetanizes frogs, or in overwhelming doses paralyzes the sensory nerves and the posterior columns. Rabbits and dogs are killed by it through paralysis of the respiratory centres. In proper doses it elevates arterial pressure by an action upon the vaso-motor centres and the cardiac-motor system."

"As a nerve-stimulant, coca has been used immemorially by the Peruvian and Bolivian natives. Its sustaining powers have been strongly confirmed by various observers both in this country and in Europe" (U. S. Disp.).

Lossen found in the best quality of coca-leaf 0.04 per cent. of cocaine; inferior material yielded only 0.016 per cent. It dissolves in 704 parts of water, but easily in alcohol, ether, and diluted acids. Its salts are soluble in alcohol, not in ether. They have a bitter taste, and cause in the tongue a transient feeling of numbness at the place of contact (Fehling).

"The coca-leaves have been recommended for almost all diseases, but the therapeutic results have proved unsatisfactory and the remedy has become obsolete. The action of cocaine is very much like that of atropine, with the difference that it does not dilate the pupil. . . . Extractum cocæ is prepared like extractum absinthii. It is said to have a dilating effect on the pupil" (Hager).

Dr. H. D. Noyes states in his communication (MEDICAL RECORD, p. 417, middle of first column): "The solution [of muriate of cocaine, two per cent.] caused no irritation of any kind, nor did it at all influence the pupil."

EXPERIMENTS WITH COCAINE ON THE EYE.—In my first experiments with a two per cent. solution upon patients during various operations I noticed no dilatation of the pupil, but trying it afterward on a patient with ocular neuralgia, and watching it longer, the mydriatic effect of the drug was manifest. The same with another patient in whom I slit a canaliculus and opened the distended lachrymal sac. Relying on Dr. Noyes' assertion and my previous observations—I had at that time not read the contradicting statements of Hager—I suspected that I had contaminated my supply of cocaine with atropine by using a dropper which had been taken from a bottle formerly containing duboisine, though I had carefully cleansed the dropper and used it in six instances without noticing mydriasis. I procured fresh supplies of cocaine in new glasses, provided with droppers that had never been used. This I used upon myself and four members of my family, watching it a whole afternoon and evening. The mydriatic effect of cocaine of a two per cent. as well as of a four per cent. solution was positive and pronounced in all. These *experiments upon myself and four other healthy persons* need not be described *in extenso*. The following may suffice:

The instillation of a two or four per cent. solution of hydrochlorate of cocaine into healthy eyes *produces no pain, nor any discomfort*. During and after its action the conjunctiva does not change its aspect; it is neither swollen nor congested. The appearance of the fundus oculi, examined ophthalmoscopically, likewise remains unchanged. The same holds with regard to the movements of the eyeball. If there is any change in the *tension* of the globe, of which I could not positively convince myself, it is rather toward a diminution than toward an increase.

The *diminution of sensibility* in the cornea and conjunctiva varies in degree in different individuals. In most cases it becomes manifest as early as three minutes after the first instillation, increases for ten to twenty minutes, then decreases, and is over in about half an hour. When another instillation is made, from ten to twenty minutes after the first, the anæsthesia is more intense, on superficial touching mostly absolute, and lasts longer. In an hour after the first instillation it becomes very feeble, and in an hour and a half it disappears.

The *pupil begins to dilate* ten to twenty minutes after the instillation, increases slowly, becomes in some persons as large as with atropia in about thirty to forty-five minutes, remains stationary for about thirty minutes, and then slowly disappears. The last trace had disappeared on the next day only.

The *range of accommodation is shortened* by moving of the near point from the eye, the far point not being appreciably influenced. The shortening of the range of accommodation was limited and differed somewhat in different observers: in myself it was equivalent to $\frac{1}{3.6}$ (1 D); in my son, fifteen years of age, about the same; in Mrs. K——, it was more. Cocaine, therefore, affects the accommodation like the mydriatics. It reduces, but does not paralyze it. It may, therefore, be preferable to other mydriatics if we want to dilate the pupil for ophthalmoscopic examinations of the interior of the eye, but it will probably not be powerful enough for determinations of refraction. It is a mydriatic which, even in producing a maximum dilatation of the pupil, takes away only a fraction of the power of accommodation. In Mrs. K——'s and my own eye astigmatism manifested itself very conspicuously; the letters appeared to slant from left to right; the left eye of both of us was "cocainized." With her the slanting was more perceptible in near vision, with me in distant vision. The letter N slanted about fifteen degrees to the right, and was turned straight by a $+ \frac{1}{7.5}$c. ax. 110°, also by a $- \frac{1}{9.5}$c. ax. 15° or 20°, the same with a $+ \frac{1}{11.4}$c. 110° ⊃ $- \frac{1}{11.4}$c. 20°.

The accommodative power was restored much sooner than the normal size of the pupil. In one and one-fourth or one and one-half hour we could read again as easily as before, though our pupils were still considerably enlarged.

Cauterization of a "cocainized" conjunctiva.—The conjunctiva of my right eye was a little congested, and at 10.30 P.M., while writing this communication, I dropped a drop of a four per cent. solution of hydrochlorate of cocaine on the inner surface of the lower lid. Fifteen minutes later I noticed that this inner surface had become pale, paler than that of the left eye, which had been the paler before. I dropped another drop in, holding my head back so that the whole conjunctiva was moistened by it. Then I painted, before a looking-glass, a good-sized camel's-hair brushful of a two per cent. solution (gr. x. ad ʒ j.) of nitrate of silver into the eye, the lower lid being everted. I left the liquid in place about twenty seconds, then it began slightly to smart, whereas immediately after the application I only felt the cold, no pain. I washed the nitrate of silver away with ordinary water, and put another drop of cocaine in. This relieved the smart for five minutes, then it returned, but very slightly; a serous liquid ran from my right nostril, just as it does when a stronger solution of nitrate of silver is put in the eye in the ordinary way. I instilled another drop of cocaine and continued writing. In a quarter of an hour the eye felt hot and somewhat painful. The conjunctiva of the lower lid was moderately, that of the adjacent scleral conjunctiva slightly, red, and along the whole lower fornix lay a white streak of mucus. The cornea and upper scleral and palpebral conjunctiva were white as if nothing had been done. The pupil was wide, and the accommodation somewhat weakened, not so much as to make writing unpleasant, though the other eye had been "cocainized" in the afternoon of the same day.

EXPERIMENTS ON THE EFFECT OF COCAINE ON OTHER MUCOUS MEMBRANES: 1. *The ear.*—I have made only one experiment in this locality. It was successful; see later, Case VIII. I do not doubt that the remedy will find here a large field of application, both to allay pain and to render the parts insensible during operations in this exceedingly sensitive cavity.

2. *The mouth.*—I can confirm the former observations that the tongue and the soft palate become numb. I sprayed and brushed my soft palate; in ten minutes I could pass instruments over it without pain or reflex phenomena, reaching, etc. I brushed a four per cent. solution over the right half of my tongue from the tip to the palate, held the tongue depressed with my finger and immovable as long as I could endure it. In seven minutes I repeated the manipulation; five minutes later the right side of the tongue and corresponding lip felt numb. Gentle touching was not perceived, but quite well on the other side. Then I put, with a fine brush, some powdered sugar on the insensible parts, successively from the tip to the neighborhood of the palate. It was not perceived, whereas when put in the same way on the corresponding places of the other half of the tongue, it was at once tasted. The same was the case when common salt and a one per cent. solution of sulphate of quinine were placed on the tongue. In half an hour all was normal again. Conclusion: *Cocaine temporarily and locally destroys not only the sensibility of the tongue and pharynx, but also the faculty of taste.* In the endeavor to suspend the sense of taste altogether, I sprayed my mouth and palate. The taste was much reduced, but not abolished, evidently because the remedy in this experiment had not sufficiently acted on all the portions of surface from which impressions of taste are received.

3. *The nose.*—I brushed and sprayed the nose to test the action of the new remedy on the organ of smell. The experiments required a good deal of time and material before they were successful. The lower parts of the nose soon had a numb feeling and were insensible to the touch, but the power of smell was preserved. Bearing in mind that olfaction is the function of the upper nasal passages, the recesses of which are very difficult of access, I bent my head down so as to make the vertex its lowest part, and introduced the bent nozzle of a Richardson atomizer in such a way that the spray was directed from the lower to the middle and upper nasal passages, and the liquid flowed also in the same direction. This manœuvre had to be repeated three times before the faculty of smell was destroyed. Perfumes of rose and heliotrope were not perceived. Tincture of iodine, concentrated nitric acid, etc., produced no peculiar sensation, whereas on the other side they felt very unpleasant and produced coughing. *Cocaine*, therefore, *temporarily renders the mucous membrane of the nose insensible and destroys the sense of smell.* In less than half an hour the whole effect of the remedy had vanished.

4. *The larynx and trachea.*—I am just suffering from an attack of acute bronchitis, with fits of troublesome coughing in the morning and evening. When one of these fits came in the evening, I sprayed my larynx with cocaine and inhaled it as well as I could by means of a Richardson apparatus. The irritation was at once allayed, and soon subsided. I had no cough, but half an hour later I expectorated, free from irritation, a large, compact, muco-purulent sputum. If this experiment should be confirmed by others, and the effect be the same or similar, cocaine will prove a great boon to patients with pulmonary difficulties. The perfected methods of introducing medicated substances by means of the ingenious apparatuses of Dr. Sass would relieve the distress of coughing and its prejudicial consequences. I may add, however, that the Richardson apparatus, which seems inadequate for this purpose, relieved me only partially in a second, and not at all in a third attack during the night.

5. *The urethra.*—My urethra is very sensitive to the introduction of instruments. I injected, by means of an Eustachian catheter and a balloon, a four per cent. solution of cocaine, and held it in for a few minutes. In ten minutes the glans had become pale and insensible to the touch. I repeated the injection. Seven minutes later I introduced a catheter and other instruments into the urethra. I did not feel them at all as far as 3″; when pushed farther I felt them very unpleasantly painful. Evidently the cocaine had not penetrated more deeply. Before the injection of cocaine I felt the instruments very keenly from the beginning of the urethra. To test the loss of sensibility of the cocainized urethra in another direction, I injected a one per cent. solution (gr. v. ad ʒ j.) of arg. nitr. into the anterior part by means of an Anel's syringe, introduced as far as 1½″. I had no sensation from it at all. In about thirty seconds I passed water, which caused a slight burning, disappearing in about a minute. Since that time I have not felt anything from the treatment of my urethra. This experiment shows, and I feel convinced, that cocaine will prove most beneficial in uro-genital surgery. It not only destroys the sensibility of the parts, and therefore admits of the easy performance of many surgical procedures, but by being painless these procedures will not incite reflex phenomena, spasm, and the like.

6. *The rectum.*—For the sake of completeness I injected also cocaine into the rectum. The sensibility, which was not great anyhow, was reduced.

In concluding this communication I will describe the

APPLICATION OF COCAINE IN DISEASES OF THE EYE,

such as opportunities have presented themselves to me thus far.

CASE I.—A young lady, suffering from convergent strabismus, had, October 15, 1884, two drops of a two per cent. solution of hydrochlorate of cocaine, just obtained from Mr. Foucar, dropped into her eye at 4 P.M., before the students of the New York Ophthalmic and Aural Institute. Three minutes later the sensibility of the cornea, tested with tissue paper and blunt probes, was unmistakably diminished. Ten minutes after the first application, when the sensibility of the cornea and conjunctiva was greatly reduced, but not abolished, two drops more were instilled. Five minutes later the anæsthesia was complete, when the cornea and conjunctiva were

gently touched, but not when the squinthook was passed high under the upper lid. Twenty minutes after the first instillation the wire speculum was inserted, the conjunctiva grasped with forceps, cut with scissors, the hook introduced, the tendon divided with scissors, and the conjunctival wound closed with a suture. All this was felt as pain by the patient, yet not very keenly. The sensibility was not abolished, but appeared blunted.

Case II.—October 16, 1884: I instilled two drops of the above solution into the eye of a lady who had a cinder in the centre of the cornea. In ten minutes the cornea was anæsthetic. I removed the cinder by means of a delicate gouge, with very little, yet not without, pain. The removal was easy.

Case III.—October 16th: The same solution instilled into the eye of a man having a pterygium. Ten minutes later, instillation repeated. The cornea and conjunctiva became insensible. During the operation—transplantation into the lower fornix and covering the defect with the adjacent conjunctiva by a stitch—the patient manifested about as much pain as this operation usually causes when performed without an anæsthetic.

The anæsthesia in these three cases disappeared almost immediately after the operation.

Seeing that the effect of the new anæsthetic in these three operations had not come up to my expectation, nor to what was claimed for it, I asked Dr. E. R. Squibb whether he could furnish me a two per cent. solution of the remedy. He sent me a four per cent. solution, remarking in a letter that the two per cent. solution had been extensively tried by Dr. C. S. Bull, and proved only partially satisfactory. He had prepared for Dr. Bull, at his suggestion, a four per cent.

Case IV.—Of this solution I instilled, on October 17th, at the New York Ophthalmic and Aural Institute, in the presence of the students, a few drops into the eye of a cataract patient, aged sixty-eight. In twenty-five minutes, during which time he had held his eyes closed, there was complete anæsthesia of the cornea and conjunctiva. I instilled a few drops more. Five minutes later I performed the extraction of cataract in the usual manner, asking the patient at every step whether he felt any pain. Only when the iris was drawn out and cut he said that it hurt him. The corneal section gave him no pain. The expulsion of the lens, which was done by pressure with a spoon on the lower segment of the cornea, required more force than usual, though the section was perfectly sufficient and the capsule not thickened. The eye appeared inelastic, so that the expulsive force requisite had to be imparted by outward pressure. The cleansing of the wound, the stroking back of the iris out of the cornea, and the adjustment of the flap with a spatula were not felt at all. When the bandage was applied the parts were still insensible, but free from all irritation. The patient had felt no pain, except when the iris was seized and cut; he laughed during the whole performance, and when it was finished he exclaimed, "What! is that all? I have scarcely felt anything." He had some pain in the first thirty-six hours, but no inflammatory irritation.

Case V.—October 18th: Mr. B——, aged thirty. Cinder in cornea, surrounded by a white ring, circumcorneal injection marked; since yesterday. Three drops of four per cent. solution. Removal twenty minutes later. Cornea insensible. The digging and scraping caused no rolling of the ball, no winking with the lids, no pain. Even when I held only the lower lid down and left the upper free, the manipulation caused no closure of the lids.

Cases VI. and VII.—October 18th: Old *trachoma*. Insensibility of cornea and conjunctiva; touched with sulphate of copper. No pain, no irritation, scarcely any increased congestion after the application. No discomfort as when touched before.

Case VIII.—October 18th: *Polypi auris* after removal of exostosis; very painful. The sensibility in scraping them out was decidedly diminished in the superficial layers, not in the depth after two instillations of cocaine.

Case IX.—October 19th: Mrs. N——, aged fifty-six. Conjunctivitis of both eyes, *tumor sacci lacrymalis* of the left. Four per cent. cocaine, six drops in conjunctival sac and on lachrymal points; ten minutes later cornea and conjunctiva anæsthetic, pupil slightly dilated. Tension of globe the same. The introduction of Weber's knife through one-half of the canaliculus is not felt, the pushing forward into the sac and slitting the inner wall of the sac, and passing a thick probe into the nose, are felt painful, but it seems less than usual.

October 19, 1884.

THE NEW LOCAL ANÆSTHETIC.

By D. B. ST. JOHN ROOSA, M.D., LL.D.,

PROFESSOR OF DISEASES OF EYE AND EAR, NEW YORK POST-GRADUATE SCHOOL.

I HAVE been using the chloride of cocoaine, as a local anæsthetic, for the last ten days, in operations upon the eye, and in one case of neuralgia of the tympanum. The preparation employed was a two per cent. solution made by Mr. Foucar. In the first case the internal rectus muscle was divided. The subject was a young woman. She experienced no pain until the muscle was taken up by the hook, and then she cried out rather lustily, but she did not become at all unmanageable. In the second case I divided both external recti and brought forward the internal rectus. The cocoaine was used in this case every five minutes for fifteen or twenty minutes before the operation, and some three or four times during its performance. The patient was a young and healthy man, a clergyman by profession. He said the pain was inconsiderable, and I had no trouble during the operation from his movements. Indeed, he seemed to suffer very little.

On the 20th I extracted a cataractous lens, in its capsule without an iridectomy, while the eye was under the influence of the new local anæsthetic. None of the stages of the operation caused anything but trifling pain. The eye remained steady and tractable to the end of the manipulations, and no accident occurred. The operation was witnessed by Dr. Vosburg, of this city, Dr. G. J. Bull, Dr. Ring, and Dr. Tewksbury. October 21st I divided the internal rectus, and employed the cocaine in the usual way, that is, two drops every five minutes for fifteen or twenty minutes before the operation, and once during it. The patient experienced considerable pain, and said she would take ether the next time.

As intimated above, I have used the drug locally—upon the membrana tympani—in one case of that rare disease, tympanic neuralgia. The patient said the pain was relieved in ten minutes after two instillations. I have used it for the operation of slitting up the canaliculi and probing the nasal duct, but as yet without any alleviation of the pain usually caused. Except in one case, dilatation of the pupil has always been produced in my cases, but no other unpleasant symptom.

Since writing the above I have performed two operations upon the eye, while under the influence of the muriate of cocoaine, with the most satisfactory results. In these cases a two per cent. solution was used, but it was instilled three to four drops at a time, every three minutes for fifteen minutes. In one of these last cases I divided the internal rectus of a boy of twelve years. He declared that the operation did not cause him greater pain than was produced by pinching the skin of his hand. The last case was one of division of both the external recti muscles in a man of about thirty-four years of age. He declared that the pain was of no consequence whatever, and talked freely with me while I was engaged upon his eye.

OVER $7,000 have thus far been collected by THE MEDICAL RECORD for the Sims Memorial Fund.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, October 25, 1884.

A PLEA FOR THE COUNTRY DOCTOR.

THE best elements of our character are always brought out by opposition. Environment determines many points of excellence which cannot be developed by any other means. It applies to the doctor as well as to others of the *genus homo*. The rural practitioner especially is full of controlling surroundings. If he gets the better of them he is so much more of a man. Every one who knows him sympathizes with him in his every-day fight, and credits him with his well-earned successes. The letter in another column refreshes a picture which is full of cold shadows and rugged outline. The central figure is the country doctor and his horse struggling through the deep trough of a muddy road, with a background of bleak hill, and trees bare-poled to meet the whistling wind. No fancy sketch, as he can tell us, but full of reality to thousands of fellow-workers. Hardly appreciated, however, by the metropolitan brother in his cushioned coupé, trundling over Macadamized avenues to sick millionaires.

But after all, taking ordinary chances, we would be inclined to side with the country doctor in any emergency occurring in general practice. A man who can extricate his horse from a snow-drift on a dark road may not be lacking in resources to dislodge an impacted fœtal head, cut the bridle of a strangulated hernia, or make a new path for a bean in the trachea. That he is accustomed to shoulder responsibility hardly tells against him in his general results. His resources widen with his opportunities, and when he makes his own path up the mountain he can the better appreciate the broadened view which he gains. If he has to swim without corks he can float with the more confidence in the deeper waters.

There is more of an education for a doctor than is comprised in the dosage of pills or the action of powders, and the country doctor gets it very often in his daily contact with man and nature. Insensibly he strikes a balance between the capabilities of the one and the power of the other. Matter-of-fact, it is true, but practical always. He may not have time to look after the countless micrococci that fill the scientific air, but he takes care that they do not obscure the view of the end of his road. His destination must be to cure his patient. If he fails, his good friends in and out of the profession will know it. Consequently he must be the general practitioner *par excellence*, as ready to brighten the headlights as to handle the tiller.

The type of the general practitioner is the self-reliant man on the dark country highway, whose every instinct teaches him to keep the road, whether it be going to a patient or at a patient.

It is truthfully said that he cannot call for help always; therefore he helps himself. It is not so much the instrument as the brains behind it. A man of sound practical sense may treat a fractured thigh sometimes better in the backwoods with a forked stick and piece of blanket than can another with an improved "Buck's extension" in a metropolitan hospital. It is the difference in the man wherever he is. The doctor in the country has the best of it because he has more chance to develop himself, and when he does it he need not envy the city man who steadies his professional standing by fastening intellectual guy-ropes to the bell-call of every neighboring specialist. These dependents are not the backbone of the profession. They can only wriggle their way to patronage while they are riding the ground-swell of the bigger fish. They could not live so well in the country. We are speaking now of the extremes of dependents and independents in their respective types of general practitioners in and out of the cities. If they were to change places specialism in the cities would suffer and general practice in the country would hardly improve. So much for the claims of the progressive, wide-awake, and self-reliant country practitioner.

Our correspondent allows the current of his enthusiastic advocacy of his class to take him slightly beyond his depth when he implies that living in the city is not more expensive than in the country, and that the metropolitan has everything he may wish for. Stop at the hundreds of signs on the avenue highways and side-street byways and ask how it is. To display such a light on a city hill is very different from merely removing the country bushel. The yearly rental of a house on an avenue would buy a country cottage, while the first cost of a coupé would cover the contract for a barn, with possibly a good horse thrown in. Where much is spent much must be earned. The ambitious metropolitan works as hard as the rustic, with hardly as good a show on the grand track. They, in fact, both need rest. Both should take it. It would do the rural gentleman as much good to visit the city in the winter, and exchange his muddy paths for dry pavements and his snow-drifts for closed cars, his patient's bedside for hospital ward and his saddle for the orchestral chair, as it would in summer for the city man to climb the hills, to sail the lakes, cast the fly, or hunt the deer. It is the change which gives the rest—the rustic may study interiors, the metropolitan develop exteriors. Both would be benefited thereby and escape the effects of that continuous drudgery which too often breaks the backbone of a noble aspiration.

THE PATHOLOGY OF LAWN-TENNIS.

FOR two or three years English medical journals have had, now and then, letters about "lawn-tennis arm," "lawn-tennis elbow," and "lawn-tennis leg." Any physician who meets many lawn-tennis players is quite sure to find some who complain of a trouble with the wrist, or forearm, or elbow. These troubles are rather more apt to occur among the beginners, since they are due to the very sudden and often unnecessarily violent muscu-

lar contractions which the too ambitious player makes. They are also rather more frequent among elderly persons. Hence we hear more of them in England, where persons of every age play tennis.

The "lawn-tennis arm," so-called, appears to be generally due to a rupture of the *pronator radii teres*. This is a slender muscle, and the sudden call upon it in using the racket sometimes does it an injury. After long practice, however, the pronating power of this muscle is very much increased and the danger of injury is less. When an accident to it occurs the victim feels pain on flexing or pronating the forearm; there is tenderness, and perhaps swelling and discoloration along its course. Doubtless the muscle in question is not ruptured entirely, but only as to some of its fibres, while coincidently there is a good deal of stretching and perhaps tearing of the fibrous and ligamentous tissues on the inner side of the elbow, near where the muscle arises.

Another form of "lawn-tennis arm" appears to be due to an injury to the musculo-spiral nerve or its posterior interosseous branch. This nerve winds around the outer side of the humerus beneath the triceps muscle and descends between the long supinator of the wrist and the brachialis anticus. In other words, it passes close to, and supplies, two muscles that are brought into powerful action in back-handed strokes. When these strokes are made too suddenly and violently by unseasoned muscles the contractions appear either to injure the extensors and supinators of the arm, tearing some of their fibres, or perhaps the nerve itself is injured by the violent squeezing which it gets. At any rate there is a quietus put upon back-hand strokes for a time.

We have seen tennis players who suffered from weakness of the wrist. The violent flexing of the fingers and wrist has in these cases stretched or torn some fibres of the anterior annular ligament, which holds the flexor tendons down. Sometimes a slight teno-synovitis seems to be set up. A firm rubber band is a great help in these cases.

Tennis players may and do suffer from ordinary sprains of the elbow or shoulder. In these there is nothing distinctive or peculiar.

Besides "tennis arms," we have "tennis legs." For example: A player while serving a ball with a powerful cut-down stroke suddenly felt a sharp pain in the calf of his leg and the leg immediately became powerless. A few days later large black-and-blue spots appeared on the calf. This patient had a "tennis leg." The trouble was caused by a rupture of some of the calf muscles. The English writers assume the affected muscle to be the small and rudimentary plantaris longus. Certainly there is more involved than this in many cases.

The treatment for all the foregoing pathological products of athletic activity is, in the main, rest, massage, and elastic compression. Sometimes the use of elastic bandages, such as Martin's, enables one to use the injured arm very soon. At other times the trouble is more obstinate, and the arm has to be given almost complete rest for a long time. When the nerve is injured, electricity is very useful. A bad tennis leg may require a starch bandage and a high-heeled shoe for a time.

In conclusion, we would say that tennis players need not feel alarmed by this description of the possible accidents in the game. The proportion of tennis arms and tennis legs is extremely small. It may even be questioned if young and perfectly healthy persons can rupture their muscles in using a tennis racket. Certainly such a thing is of rare occurrence. But non-athletes who take up tennis after thirty should be a little careful.

THE NEW YORK STATE MEDICAL SOCIETY.

Circulars have been issued by Dr. B. F. Sherman, President of the New York State Medical Society, requesting that the titles of papers to be read at the next meeting be sent in by the first of December. It is desired that the full list should be published at that time, so that the discussions may be full and exhaustive.

The object of the President is praiseworthy, but he will not attain it by the method alone which he proposes. If the titles of any large proportion of the papers could be obtained so early as December 1st, which is doubtful, members would be very likely to forget them before February. Apart from this, however, every one knows who has attended State meetings that more radical changes must be made in order to secure valuable discussions. At present, there are generally too many papers for the time of the Society. The discussions have to be cut short, instead of being encouraged. Nor is there any systematic attempt to get good discussions. Experience with medical men and medical meetings shows that it is only rarely that good discussions are secured without previously canvassing members and seeing that those who can speak instructively are present and prepared.

It is possible that at the next meeting, with the Code question no longer to vex us, there may be time for the full presentation and consideration of papers. If not, however, some radical change must be made. Sections must be established—a measure of questionable wisdom—or the meetings prolonged, or the number of papers accepted must be more carefully limited.

The practice of urging readers of papers to have printed slips of an abstract for distribution to the members sometimes increases the interest in papers that are long or very technical, and the question of its adoption should be borne in mind by the Business Committee.

SUITS ARISING OVER INJURIES.

The suits arising over injuries incurred in accidents, especially those connected with railroad collisions, often bring up the question of the skill of the attending physician or surgeon, and the railroad companies lay great stress wherever possible upon the alleged incompetence or negligence of the professional attendant. If this defence were allowed to the extent it is sometimes pushed, the poor victim of a collision would be obliged to warrant that the utmost skill had been exercised by the surgeon, or else he could not recover any damages. This is not the rule adopted by the courts, which generally hold that all that can be legally exacted of the sufferer is ordinary care and skill in the choice of an attendant. A recent case in Pennsylvania states this principle, where the injury was a broken arm, and the ruling of the judge was as follows: "There is evidence tending to show that, had this broken arm received ordinary care and ordinary professional skill,

the parts would have united with little or no permanent injury, and on this hypothesis alone appellant insists that the matter of this false joint should have been, at least hypothetically, excluded from the jury. We understand the law on the subject to be that plaintiff cannot hold defendant answerable for any injury caused, even in part, by the fault of plaintiff in failing to use ordinary care or ordinary judgment, or for any injury not resulting from the fault of defendant, but caused by some new intervening cause not incident to the injury caused by defendant's wrong. Thus, in this case, if it be conceded that the false joint, under proper care and skill, would not have resulted from the breaking of the arm alone, but was brought about by the subsequent separation of the parts after they had been properly set, and before nature had formed a firm union, then if this subsequent separation of the parts had been caused by an assault and battery by a stranger, or some foreign cause with which appellant had no connection, and which was not in its nature incident to a broken arm, plainly appellant ought not to be held to answer for the false joint; but if appellee exercised ordinary care to keep the parts together, and used ordinary care in the selection of surgeons and doctors, and nurses, if needed, and employed those of ordinary skill and care in their profession, and still by some unskilful or negligent act of such nurses, or doctors, or surgeons, the parts became separated and the false joint was the result, appellant, if responsible for the breaking of the arm, ought to answer for the injury in the false joint. The appellee, when injured, was bound by law to use ordinary care to render the injury no greater than necessary. It was, therefore, his duty to employ such surgeons and nurses as ordinary prudence in his situation required, and to use ordinary judgment and care in doing so, and to select only such as were of at least ordinary skill and care in their profession. But the law does not make him an insurer in such case that such surgeons, or doctors, or nurses, will be guilty of no negligence, error in judgment, or want of care. The liability to mistakes in curing is incident to a broken arm, and where such mistakes occur (the injured party using ordinary care), the injury resulting from such mistakes is properly regarded as part of the immediate and direct damages resulting from the breaking of the arm."

PALLIATIVE MEASURES IN RUPTURED EXTRA-UTERINE PREGNANCY.

Another woman has passed from health to the grave in a few hours; another home has been made desolate; and another victim to delay and palliative hypodermatics of morphia and brandy-and-water in drachm doses has been added to the list, already too long, of cases that have been lost for want of surgical treatment.

A case has been recently reported, in a Western medical journal, in which the symptoms of rupture of an extra-uterine fœtal sac were complete, and the diagnosis of extra-uterine pregnancy was concurred in by three practitioners, and the following treatment adopted: "Sulphate of morphia in one-sixth-grain doses, hypodermatically, to control the pain, and brandy, both by the mouth and under the skin, as a stimulant. A sinapism over the stomach and bowels assisted in giving some measure of relief." The patient died in sixteen hours and a half. Nothing is said of an attempt to control the hemorrhage, which every one must have known was draining away the woman's life. Nothing is said of a desire to open the abdominal cavity to stop the hemorrhage and remove the foreign body. Is the recorded experience and the teaching of the surgical leaders of the day to go for nothing? Are there any who think that a patient in this situation dies of aught else save hemorrhage, and controllable hemorrhage? If the hemorrhage be not controllable, why do the patients live for sixteen and twenty or thirty hours after the rupture? Are there those in the profession who do not know that the mere exposure of the abdominal cavity to the air will often check a hemorrhage which would otherwise prove fatal in the closed cavity? Surely in these days of great and brilliant triumphs in abdominal surgery, when patients recover after intestinal wounds and resections, when the most desperate "forlorn hopes" recover, one should not hesitate to open the abdomen in a case of this kind, when two or three ligatures and some clean water are all that are required.

There is no palliative measure for a ruptured extra-uterine cyst; there is no expectant treatment; and there is no other way known to medicine by which a woman in this condition can be reasonably expected to survive save by the prompt use of the knife—and there is no reason for thinking that she would die if this be resorted to in time. And until she is practically dead it is never too late to try and save her.

MR. VANDERBILT'S GIFT.

The College of Physicians and Surgeons deserves warm congratulations upon the magnificent gift of half a million dollars which has been so generously made to it by Mr. William H. Vanderbilt. Such a donation is unprecedented in the history of American medical colleges. It places the fortunate institution among the few endowed medical colleges in this country, and will enable it to carry out the efforts at a higher education which it has already shown itself desirous of making.

The medical colleges in this country which, in 1881, had productive funds were the following: Yale Medical College, $29,102; Harvard Medical School, $280,391; Medical Department of University of Pennsylvania, $50,000, and Johns Hopkins Medical School (not yet open). Besides these, the McHarry Medical College, the Howard University Medical School, and the Kansas City Medical College have small endowments; while several others, such as Dartmouth and Bellevue, have had large sums of money presented for specific purposes. A number of Western medical colleges also give tuition free and are supported entirely by the State.

The Faculty of the College of Physicians and Surgeons of New York already has property valued at nearly $200,000. With its recent gift, therefore, it becomes the richest institution of the kind in America. It is announced that the money will be used, in part at least, for the construction of a new building, which will be erected in the northwestern part of the city, in the vicinity of Roosevelt Hospital. Such a move, if made, will be a bold one, since tradition has heretofore located medical instruction upon the east side of the city. By

the enlargement of Roosevelt, the construction of a maternity hospital, and the development of dispensaries, the part of the city referred to could probably, in time, be made another medical centre.

Roosevelt Hospital, however, will meanwhile have to undergo some radical and needed changes in the arrangement of its visiting services. For although it is admirably managed in a way, nevertheless in usefulness to medical and surgical science, and for the purposes of practical instruction, it has been falling behind.

News of the Week.

Muriate of Cocaine in the Operation for Cataract.—The operation for double senile cataract was successfully performed this week at Mount Sinai Hospital, muriate of cocaine being used, and no general anæsthetic. The patient experienced no pain.

A Journalistic Change.—It is announced that *The Therapeutic Gazette* will be moved to Philadelphia, where it will be edited by Professor H. C. Wood and Professor Robert Meade Smith. *The Gazette* will still be published by Mr. George S. Davis, of Detroit, whose liberality and energy have already done so much for it. We welcome Professor Wood back to the field of journalism. His editorship insures to the profession a journal in the interests of scientific pharmacology as well as of practical therapeutics.

The Hospital Saturday and Sunday Association held its first meeting for the fall during the past week. A report was made by the general agent of the Society, Mr. F. J. Cook, in which it was stated that the work was well advanced, and that there was an excellent prospect. There would, in all probability, be a larger collection from the churches than heretofore. The members of additional trade auxiliaries had been brought into the work, having been organized during the summer.

The So-called Gonococcus Normally Present in the Healthy Urethra.—Dr. E. C. Wendt, of New York, writes that with the aid of a suitable instrument he has examined the scrapings from different portions of the healthy male urethra. In every instance these scrapings were found to contain, in greater or less abundance, micrococci morphologically identical with Neisser's so-called gonococci. The inference is obvious. He intends at a later date to publish the detailed results of a large number of observations, which, in conjunction with Dr. C. W. Allen, of New York, he has already made, and is still engaged in making.

Washington Obstetrical and Gynecological Society.—At a regular meeting of the Washington Obstetrical and Gynecological Society, held October 17, 1884, the following officers were elected for the ensuing year: *President*—Samuel C. Busey, M.D.; *Vice-Presidents*—W. W. Johnston, M.D., and J. Taber Johnson, M.D.; *Recording Secretary*—C. H. A. Klineschmidt, M.D.; *Corresponding Secretary*—Samuel S. Adams, M.D.; *Treasurer*—George Byrd Harrison, M.D.

Dr. Domingo Orvananos, the Secretary of the Board of Health of the City of Mexico, has been in this city studying our methods of sanitary administration.

Death of Professor F. A. Ross.—Dr. F. A. Ross, of Mobile, Ala., died October 17th, of apoplexy. He was born in 1821, and was graduated at several institutions of learning, including the University of Virginia and the Pennsylvania Medical College. He served as Surgeon of the Palmetto Regiment during the Mexican war, and during the war of the rebellion was the Medical Director of the Department of the Gulf, under the Confederate Government. He was at one time President of the Mobile Medical Society and of the Alabama Medical Society, and Professor of Therapeutics in the Mobile Medical College.

"Dead Teeth in the Jaws."—Dr. C. E. Nelson writes: "In my communication to you on this subject (October 18, 1884), on page 444 of The Record, I notice two important typographical errors, which I should like corrected. In the second column, line 25 from bottom, for *nominally* read *normally*. In line 8 from bottom, for *than* read *then*."

The New York State Medical Association.—The Fellows and delegates of the New York State Medical Association assemble in this city on the third Tuesday in November next (the 18th). The Association is at present composed of 168 founders, representing 40 out of the 61 counties of the State. Half of the founders come from six counties, New York having 33, Rensselaer County coming next with 14, and King's County last with 7. Sixteen counties have one representative. It has been voted to call the members Fellows. A committee, consisting of Drs. A. Flint, Jr., Van de Warker, and Gouley, has been appointed for the purpose of securing the co-operation of a medical journal in harmony with the objects of the Association. It has been voted that members who are to read papers shall have a synopsis printed for distribution. The main object of the Association is to secure to the profession in New York State representation in the American Medical Association. The question will, therefore, doubtless be raised whether those counties in which medical societies have not changed their old code and which are still entitled to representation can send a double set.

The Report of the French Cholera Commission at Marseilles.—This commission, consisting of seven members, of whom only five acted, viz., MM. Sicard, Taxier, Loucel, Livon, and Chareyre, offers the following conclusions: "1. The cholera is transmissible to the rabbit, as demonstrated by injection into the veins of the blood of a cholera-patient at the algid period. The rabbit died in twenty-four hours, with lesions entirely like those of cholera. 2. By cultivation, this blood after a few hours loses its infectious properties. 3. Injections of choleraic blood in the period of reaction, or a very advanced algid period, produce no effect. 4. The perspiration of a cholera-patient, injected into the veins, does not transmit cholera. 5. The stomachic or intestinal dejections, or the gastro-intestinal contents (this last full of comma-bacilli), may, after filtration, be injected with impunity into the cellular tissue of the peritoneum, the windpipe, the intestines, the rectum, and even into the blood. 6. Comma-bacilli taken from the intestines of a cholera-patient may be introduced into the intestines of a rabbit, and multiply there for more

than eleven days, without producing any choleraic symptoms, and without necropsy revealing the anatomo-pathological lesions characteristic of cholera. 7. There is thus every proof of the non-specificity of the comma-bacillus. We experimented on bacilli taken from the intestine, and with dejections kept from two to twelve days, the results being always negative. Everything also proves that this bacillus does not produce in the intestine toxical ptomaines which would be the cause of poisoning—namely, the lesion of the blood. The inference from more than fifty of these experiments is the non-contagiousness of cholera, which we maintained from the very opening of the discussions. 8. The minute examination made by us of the heart and large venous vessels of cholera-patients enables us to affirm that there is no phlebocarditis in cholera, as alleged by Morgagni and still maintained by many enlightened physicians. 9. Bulbar and medullary lesions, or those of the solar plexus, appear to us to be all secondary lesions. 10. In our opinion, the initial lesion of cholera takes place in the blood. 11. It essentially consists in the softening of the hæmoglobin, which makes some corpuscles lose first their clear shape, the fixity of their form, and the faculty of being indented. Those corpuscles adhere together, lengthen out, stick together, and, in very rapid cases especially, some are seen which are quite abnormal, while others appear quite healthy. 12. The entire loss of elasticity of the corpuscle (which is shown by the preservation of the elliptic form when it has been stretched out) is, in our view, a certain sign of the patient's death. To stretch out a corpuscle, it is merely needful to alter the inclination of a plate on which a sanguineous current has been established in the field of the microscope. The fluid column stops at one point, whereas the rest continues to flow. An elongation of the intermediary corpuscles results, and then a rupture of the column. In the gap thus formed are some scattered corpuscles. If these revert to their primitive form the patient may recover. If they keep the elliptic form, we have seen death follow in every case, even if the patient's symptoms were not serious at the time of the examination of the blood. At the outset, and in the rapid cases, which give the clearest results, corpuscles remaining healthy are seen alongside the unhealthy ones, and assume the shape well known in heaps of money, or maintain their liberty. When currents are created in the field of observation, the columns of healthy, or less unhealthy, corpuscles remain stationary, or nearly so; whereas the unhealthy corpuscles flow between the columns or the stationary masses like fluid lava. This we believe to be the characteristic lesion of cholera. By hourly examination of the blood of cholera-patients the progress of the malady can be mathematically followed. First some corpuscles are unhealthy, then one-third, then half, then two-thirds, and lastly death supervenes. A very important fact in our view is that all the corpuscles are not simultaneously affected. We debar ourselves from substituting a fresh hypothesis for all those we have overthrown. We confine ourselves to saying that we know better than our predecessors what the cholera is not, but we do not know what it is."

The Ambulance Service in New York.—A correspondent of the *British Medical Journal* writes: "Each of the principal hospitals of New York supports one or more ambulances, which may be called by the telegraphic or district messenger systems, and are always accompanied by a surgeon. During the year ending June, 1883, Chambers Street Hospital (2 ambulances) answered 2,124 calls; the New York Hospital (2 ambulances) answered 1,118 calls; Bellevue Hospital (4 ambulances) answered 2,606 calls; Presbyterian Hospital (1 ambulance) answered 500 calls; Roosevelt Hospital (2 ambulances) answered 750 calls; Ninety-ninth Street Hospital (2 ambulances) answered 800 calls; and St. Vincent's Hospital (2 ambulances) answered 1,100 calls—showing that, during the time specified, seven hospitals, supporting fifteen ambulances, answered 9,198 calls."

Death of Dr. Louis A. Dugas.—Dr. Louis Alexander Dugas died at his home in Augusta, Ga., on October 19th. He was born in Washington, Ga., January 3, 1806. Then he pursued a course of study in the medical department of the University of Maryland, from which he graduated in 1827. He passed four years in a study of European medical institutions, and finally settled down to the practice of his profession in Augusta. He united with five other physicians in 1832 in founding the Medical College of Georgia, and accepted the chair of Professor of Surgery. He retained this position until the close of his life. In 1834 he was elected to membership in the Geological Society of France. The University of Georgia conferred the degree of Doctor of Laws upon him in 1869. He held a membership in numerous literary and scientific societies in Georgia, and was President of the Medical Societies of the State and of the City of Augusta respectively, for several years. During the international Medical Congress at Philadelphia in 1876, Dr. Dugas was one of its Vice-Presidents. He became the editor of the *Southern Medical and Surgical Journal* in 1851 and retained the position for seven years.

Bequest to the Massachusetts General Hospital.—The late Francis P. Hurd, of Wakefield, Mass., bequeathed $10,000 to the Massachusetts General Hospital.

Hospitals at Winnepeg.—Dr. Henry H. Chown, of Winnepeg, Manitoba, writes in an unnecessarily indignant tone regarding an item in The Record, which says that Winnepeg having a medical school "is about to start a hospital." Our correspondent says that the hospital which is about to be started is not the first but the third in that city, and that it is doubtful if any college has started with greater hospital advantages than the Manitoba Medical School. We are very glad to learn this, and to correct any misapprehension regarding the educational facilities of Manitoba.

"Lady Medicals."—Such are the honeyed words with which the Englishman refers to the women doctors. *A propos* thereof says one journal: "Although the Medical School for Women in London has been open some eight or nine years, only some score or so of lady doctors have been launched upon mankind, but this limited supply has far exceeded the demand, at least as far as England is concerned. Only about two or three lady doctors, I am told, can earn a living by the private practice of their profession in this country."

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, October 8, 1884.

GEORGE F. SHRADY, M.D., PRESIDENT, IN THE CHAIR.

DR. T. MITCHELL PRUDDEN presented, in behalf of a candidate, a specimen of *chronic endocarditis.*

CARCINOMA OF THE STOMACH.

DR. SATTERTHWAITE presented the stomach, pancreas, kidneys, and a portion of the lungs, removed from the body of a man fifty-three years of age. He was called on September 7th, in consultation, to see the patient, who had had a hemiplegic attack of moderate character, and from which he recovered within twenty-four hours to such an extent as to be again able to use his right upper and right lower extremities. Attention had been called to the fact that he had been losing strength rapidly for six months, and on further inquiry it was found that he had been losing flesh for two years. Up to about one month previously he had suffered from nothing especially except chronic gastritis with frequent attacks of vomiting and great difficulty in taking food. There was some pain in the epigastric region, but not severe. The urine, lungs, and heart were normal. The epigastric difficulty increased during the last month, but he had not vomited blood; nothing except the material taken. There was no tumor in the epigastric region, although it was thought that some dulness on percussion could be detected. The patient presented a cachectic appearance, and there was progressive emaciation with reduction of weight from 160 to a little more than 100 pounds.

Two months after his first attack of hemiplegia a second attack occurred, in which there was some difficulty in swallowing and speaking, but it largely disappeared, although he never fully recovered his voice or power of swallowing solids. During the last four or five days of his life the patient refused to eat on account of the inability to retain food and of the extreme pain which it produced, and he said that he preferred to starve to death, and he did starve to death.

On opening the abdominal cavity the stomach was found essentially in its normal position. At the pyloric extremity there was a patch of considerable thickening about the size of a silver half-dollar, limited to the anterior side. The pyloric orifice admitted only a lead-pencil of ordinary size. The circular patch of thickening could hardly be appreciated except by the touch. Although the constriction at the pyloric orifice was not great, Dr. Satterthwaite accounted for the gastric symptoms on the ground that the thickened portion of tissue was limited to one side, and was thrown over the orifice at times, acting somewhat like a valve.

The pancreas was infiltrated with small nodules; the mesenteric glands were somewhat enlarged. The liver, the lungs, and the heart were essentially normal. The kidneys were somewhat fatty and slightly enlarged.

The question to be determined was whether or not the thickening at the pyloric extremity of the stomach was due to malignant disease. Dr. Satterthwaite proposed to examine the specimens microscopically, but he preferred to exhibit them to the Society while they were in a fresh condition.

THE PRESIDENT asked how long after taking food the vomiting occurred.

DR. SATTERTHWAITE said from twenty-four to forty-eight hours. The spasmodic efforts during the attacks of vomiting were exceedingly severe, and probably during some of these attacks cerebral hemorrhage was produced sufficient to give rise to the hemiplegia.

DR. JOHN C. PETERS asked if the thickening was confined to the single patch mentioned.

DR. SATTERTHWAITE replied that it was confined to the circular patch which could be felt but not seen, and in reply to another question said that the stomach was not especially enlarged, although we might expect dilatation with obstruction at the pylorus, yet that does not always occur with cancer.

THE PRESIDENT remarked that it would seem, if it were malignant disease, it should have made more progress during the two years it had existed.

DR. SATTERTHWAITE remarked that he had the records of a case in which a nodule at the pyloric orifice of the stomach was felt for two years, and the history of the tumor extended back of that, and at the autopsy it was proved to be cancerous in character.

DR. JOHN C. PETERS thought that the case might prove to be a duplicate of the first case presented to the Society in 1844, one of thickening of the stomach, which was diagnosticated during life as cancer. The patient had many of the symptoms which Dr. Satterthwaite had mentioned, and there was found a hardness in the walls of the stomach without tumor, and after death it was supposed to be cancerous. On examination, however, it was found to be merely a thickening of the cellular tissue. It was regarded as a rare specimen.

THE PRESIDENT remarked that it would be interesting to ascertain whether or not cancer was frequently limited to such a small portion of the stomach.

DR. VAN GIESON said the duration of the disease was a very uncertain factor, because a malignant growth might engraft itself upon chronic gastritis.

DR. W. M. CARPENTER referred to a case in which he found at autopsy a cancerous nodule, about an inch and a quarter in diameter, situated about three inches from the pylorus, upon the posterior surface of the stomach, which had not given rise to symptoms. The patient entered the hospital and died of a disease not referable to the stomach.

DR. SATTERTHWAITE referred to a case in which he made an autopsy and found a tumor as large as an orange, situated in the greater curvature of the stomach, which had discharged by a sinus leading through the abdominal wall, and this sinus had been treated by a surgeon with the result of producing a partial cure. The patient was suddenly attacked with gastric symptoms and died. The tumor was not discovered during life, nor had the patient complained of gastric symptoms other than those which were referable to the sinus which communicated with the growth.

THE PRESIDENT remarked that it was rather the rule than the exception, when the disease was not located in one of the extremities of the stomach, that vomiting and other stomach symptoms did not develop, and that the growth was discovered only at autopsy.

NASO-PHARYNGEAL FIBRO-SARCOMA.

DR. R. P. LINCOLN presented a specimen with the following history (see page 455):

THE PRESIDENT remarked that there was no comparison between the operation described by Dr. Lincoln and that with preliminary tracheotomy, tamponing the pharynx, and removing the upper jaw. There could be no argument against the success obtained in Dr. Lincoln's case.

DR. HOWE thought that it afforded a strong argument against the use of the knife in all of these cases.

THE PRESIDENT remarked that in some cases the wire could not be applied to the base of the tumor so as to grasp it. He had had two such cases, in one of which Dr. Howe assisted at the operation, and in which preliminary tracheotomy was performed, the pharynx tamponed, and the upper jaw removed. It was found that the tumor had prolongations extending up into the skull through the foramen lacerum medius, and from this circumstance he had been enabled to explain the shock which ultimately caused the patient's death. The tumor was extensively attached to the basilar process and to adjoining portions of the base of the skull in various direc-

tions. In that case, however, the application of the wire was found to be impossible.

The second case was one in which there were almost as extensive attachments of the growth, and the operation was followed by the same result, although death did not take place as soon as in the first case. He also had another patient who was begging for a similar operation, a man twenty-two years of age, and concerning whom he had promised himself the pleasure of a consultation with Dr. Lincoln as to the feasibility of the use of the galvano-cautery. The great trouble with most of these cases was that they did not reach the general surgeon until they were beyond all hope of removal by the wire, and they were also in a very unfavorable general condition for the radical operation. There could, therefore, be no argument against success in such cases, however obtained.

Dr. Howe suggested that, even in the bad cases spoken of, before any attempt was made to remove the tumor by the knife, efforts might be made to destroy it piecemeal by means of the wire. He could not see why it could not be done there as well as elsewhere.

The President remarked that the difficulty consisted in the inability to get hold of pieces of sufficient size. Within the last year he had had a patient under observation, and had sent him to a gentleman well skilled in this method of operating, who succeeded in removing small pieces, but left the patient in such a deplorable condition from subsequent inflammation that he declined to have the operations repeated.

Dr. Satterthwaite said that it seemed to him that Dr. Lincoln's operation was an extremely brilliant one, and was one which required and obtained a great deal of manual dexterity in preventing the wire from twisting, and also in adjusting it to the base of the tumor. Dr. Lincoln passed the wire all the way down to the basilar process and removed the entire growth at one operation. It had been said by one distinguished throat specialist who saw the case that the operation could not be performed, and that removal of the upper jaw would be necessary. Dr. Satterthwaite thought that fact should be borne in mind in estimating the brilliancy and feasibility of the operation; and also the additional fact should be recollected that this was only one of three or four cases in which Dr. Lincoln had removed large naso-pharyngeal polypi, and in none of them had the disease returned.

In his hospital notes he had not found the records of a case in which the disease had not returned and the patients had been subject to hemorrhages, etc. But the patient upon whom Dr. Lincoln operated and removed the specimen presented had gained flesh remarkably, and had not had any hemorrhages whatever. In these cases the galvano-cautery is peculiarly successful because it arrests hemorrhage and destroys the tissue to such an extent that if the growth return, hemorrhage is not likely to ensue from the use of the wire. He thought too much could not be said in favor of this mode of operating, and he would be pleased to hear from Dr. Lincoln as to what his success had been.

Dr. Lincoln said he had operated in six cases. Two of the patients were still under treatment. Of the other four cases, one was operated upon in 1874, one in 1875, one in 1879, and one in 1880. He thought there was no possibility of recurrence in any of these four cases. He had not had any fatal cases.

With regard to the operation, he would refer to the one which he performed in 1875. It seemed to be as extreme a case as could possibly exist. The patient had been operated upon by Dr. Willard Parker, and also by Dr. Lutkins, of Jersey City, who sent him to Dr. Lincoln. The patient was a boy ten years of age, who, when he saw him, weighed sixty-eight pounds, and death seemed inevitable. The growth had caused the right eye to protrude a great deal, the right nostril was very broad at the base, the mouth was so filled that the uvula was carried orward to an extent that if the incisor teeth could have been closed they would have cut it off, and in general condition he was reduced to *extremis*. Dr. Lincoln made a preliminary treatment by electrolysis, with some twenty or twenty-five applications, and the result was arrest of the growth, preventing hemorrhages, and reducing the mass to such a size as to give the patient a chance to recuperate preparatory for the radical operation. At the time he operated, in 1876, the boy weighed one hundred and three pounds, and the tumor had largely disappeared from the mouth. He removed the growth in the manner already described, and without any hemorrhage. He made six applications with the galvano-cautery to the stump at invervals of one or two weeks. There had been no return of the disease. There were extensive adhesions of the growth to the back of the pharynx and the sides of the nostrils.

In another case there were prolongations of the growth to such an extent that the tumor appeared under the cheek as large as a pullet's egg. This patient was operated upon in the same manner, was put upon the same after treatment. The result was the entire disappearance of the prolongations of the growth in the face, and the patient is now perfectly well. The other cases were similar, but not so pronounced.

Dr. Van Gieson asked if in the case operated upon in 1876, where the tumor protruded so extensively into the mouth, if Dr. Lincoln was able to remove the whole of the mass through the mouth without dividing it.

Dr. Lincoln answered that the entire tumor was removed through the mouth.

The President remarked that he was so favorably impressed with this operation that he should not try any other without first attempting to use the wire, and further, that no small degree of credit was due to Dr. Lincoln for demonstrating this comparatively simple and yet radical operation.

FIBRO-CYST OF THE UTERUS.

Dr. T. Mitchell Prudden presented a specimen for which he was indebted to the courtesy of Dr. C. C. Stockard, of Columbus, Miss. The case has already been reported. (See The Medical Record, August 16, 1884.)

Dr. Prudden had submitted the growth to microscopical examination; found it to be composed of smooth muscular and fibrous tissue, presenting very much the appearance seen in the ordinary fibromyomata of the uterus. There was no distinct cellular lining of the cavity of the tumor. He presented the specimen because of its size and because it was interesting as showing one of the modes of formation of cysts, namely, softening, and perhaps dilatation of the original solid tumor by the accumulation of fluid and disintegration of tissue. The entire weight of the mass, as reported by Dr. Stockard, was one hundred and thirty-five pounds.

Dr. Ferguson remarked that he had just come from a post-mortem examination in which he removed a tumor weighing more than the one presented. It was, however, an ovarian tumor.

Dr. Castle referred to the case of a patient who died in Bellevue Hospital, where, owing to the failure of taking proper precautions, the woman by some of her movements caused the tumor to fall out of bed and it dragged the patient with it.

Dr. Wilcox asked with regard to the frequency of the occurrence of uterine fibro-cysts in the negress.

Dr. Prudden said that large tumors like this were rare, but that small tumors were not at all infrequent.

Dr. Castle remarked that it had been said to be the rule rather than the exception to find fibrous tumors of the uterus in the negress.

INTESTINAL OBSTRUCTION—UTERINE FIBROIDS.

Dr. C. W. Knight presented a specimen with the following history: A. B——, colored, unmarried, thirty-five years of age, has always been constipated, and has had frequent attacks of severe "colic" (?); has never had

occasion to call a doctor for these or for other illness. Bowels have not moved for nearly three weeks. Five days ago began to take purgatives, and has used them since in great variety, without effect. Stomach became swollen, and three days ago vomiting began. Called a physician, who gave a cathartic. No constitutional disturbance was noticed, although there was intense thirst. Vomiting became more frequent; the vomited matter was fluid and had a greenish color. During the last twelve hours of life "several quarts" were vomited, the abdomen became enormously distended, and respiration was greatly impeded. Death took place suddenly as the patient was attempting to rise from bed. The patient had been walking about her room nearly all day, making no complaint of pain, but suffering great discomfort from the vomiting and the distention of the abdomen. Enemata of various kinds were resorted to, but they brought away only a few scybalous masses. On opening the abdomen the small intestines, intensely congested and distended, were exposed. The colon was found nearly empty. About five inches from the cæcum the ileum was found constricted by a band of tissue running between two uterine fibroids. The loop of intestine was five to six inches in length, was almost black, and was distended with gas; it was easily emptied and pushed back through the constricting band. There was no ulceration, but the points of constriction were indicated by deep furrows in the wall of the intestine. The uterine fibroids, mural and sub-peritoneal, four or five in number, vary in size from that of a hickory-nut to that of a small orange. They and the cæcum and the first five or six inches of the ileum were matted together by old peritonitis. There was no ulceration of the intestine, and recent peritonitis was limited to the region of the strangulation.

The Society then went into executive session.

THE NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 16, 1884.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

DR. HARRY MARION SIMS presented a

BRONZE BUST OF THE LATE J. MARION SIMS, M.D., LL.D.,

copied from a marble bust made by Dubois, the celebrated French sculptor. It is a most life-like figure.

THE PRESIDENT, in behalf of the Academy, accepted the gift with appropriate remarks.

DR. WM. T. WHITE offered a resolution tendering the thanks of the Academy to the donor for his beautiful and highly acceptable gift.

DR. JOHN SCOTT, of San Francisco, was introduced to the Academy and invited to a seat upon the platform.

DR. WM. H. DRAPER then delivered a

MEMOIR OF THE LATE WILLARD PARKER, M.D., LL.D.,

in which he paid a worthy tribute to the distinguished citizen, the skilful surgeon, and the upright man whose "face was always set before the light."

THE THERAPEUTICAL EFFECTS OF THE INTERNAL ADMINISTRATION OF HOT WATER IN THE TREATMENT OF NERVOUS DISEASES.

DR. A. L. RANNEY read a paper with the above title, in which he maintained that the benefits following the internal use of hot water were due almost entirely to heat, and gave the following rules for its administration:

1. An ordinary goblet contains about ten ounces, and the quantity may be from one to one and a half goblet.

2. The water may be flavored with lemon, etc.; fifteen minutes may be consumed in sipping a gobletful; wooden cups prevent it from cooling quickly; and it must be taken *hot and not warm*—from 110° to 150° F.

3. It must be taken one hour and a half before each meal, with absolute punctuality, and at bed-time.

4. Increase the temperature of the water as fast as the patients can bear it.

5. The administration of hot water must be continued for at least six months to get its full effects.

6. The dose should be determined largely by the specific gravity and general character of the urine. The object is to bring the specific gravity of the urine to the standard of health.

7. The use of cold fluids in the form of beverages must be absolutely prohibited.

8. Constricted diet is often necessary to the full effects of the treatment in some form of nervous derangements.

The effects of the treatment were set forth as follows: 1, the first effect is the production of a sense of warmth in the stomach, attended by eructation of gas not infrequently; 2, the skin soon shows the effect of the heat; 3, the kidneys exhibit marked effects, and very soon the quantity of urine is increased. On the other hand, in diabetes the quantity of urine is diminished; 4, the accessory organs of digestion, the pancreas, and the liver are stimulated, and flatulence and constipation seem to be relieved.

The author of the paper then referred briefly to the histories of several cases of different diseases which he had treated by the internal administration of hot water, perhaps combined with other remedial agents.

Among these were locomotor ataxia, neurasthenia, gastralgia, local anæmia of the brain with transient aphasia, etc.

The *theory of its action* which the author of the paper advanced was that the nerves of the stomach, possibly the solar plexus, were directly influenced by the heat introduced into the empty organ. He believed that ice-water did more harm than tobacco and alcohol.

Dr. Ranney reached the following conclusions: (1) The plan of treatment is harmless; (2) its effects are comparatively uniform when given for a sufficient length of time; (3) it seems to exert a curative influence in many chronic diseases; (4) it appears that the curative influence of hot water is not transient; (5) it may be employed as an adjunct without detriment to the influence produced by other therapeutical agents; (6) it has a marked influence on the vascular disturbances of the nervous system; (7) in diabetes and some kidney affections he had seen it exert a marked influence for good, and the specific gravity of the urine had been his guide in estimating the effects produced; (8) as a laxative it has a slow but decided action; (9) the skin is stimulated and the cutaneous circulation rendered more uniform.

The author of the paper also recommended the use of hot water in sea-sickness.

DR. E. C. SEGUIN had had but little experience in the use of hot water, and had never employed it in the treatment of purely organic disease of the nervous system. He had been struck with several points in the paper which seemed to him to be open for discussion, and perhaps for some degree of question. First, as to the quality of the agent. It seemed to him that a temperature of 110° to 150° F. would hardly justify classifying hot water as a really heating agent, the internal temperature of the human body being about 100° F.

In the second place, as to the cases brought forward by the author of the paper, a large proportion of them seemed to be cases of neurasthenia, so-called cerebral hyperæmia, anæmia, etc. Many of them constituted one of the most doubtful classes in our classification of disease. Most of these disorders, certainly many of those commonly called cerebral hyperæmia and cerebral anæmia, were nothing more than cases of mal-assimilation in which the digestive organs were at fault, and in these cases Dr. Ranney had employed a combined treatment; combining hot water with strict regulation of the diet, and in some instances restriction to a purely meat diet.

Dr. Seguin suggested a question, namely: Was it not possible that the beneficial effect produced in Dr. Ranney's cases was due to water and not to hot water?

Many patients had a lack of desire for water—what Dr. McElroy, of Zanesville, Ohio, had called hydroadypsia, and many of the symptoms of spinal irritation, so-called cerebral hyperæmia, neurasthenia, etc., could be largely relieved by the internal administration of ordinary water. Hot water might do good as water in aiding assimilation, but it might be a question whether or not the benefit resulting was due to anything more than the water.

With respect to the use of hot water in organic nervous disease, he had had no experience.

Concerning the theory advanced by the author of the paper, namely, that the water produces its beneficial effect through reflex action, Dr. Seguin thought there might be some foundation for it; but at the same time, if a share of the good effect was to be attributed to the liquid, the share which could be attributed to the effect produced by the heat was not very great. He doubted if the degree of heat was sufficient to produce more than temporary hyperæmia of the mucous membrane of the stomach.

He offered a word in defence of cold water, and saw no objection to the use of ice-water upon the same principle with which he questioned the degree of heat. He did not believe that ice-water, ice-cream, etc., were exceedingly cold when they reached the stomach, for they received a large amount of heat in their passage through the mouth and œsophagus.

In point of fact, he had obtained just the same results by the use of ordinary water as those which Dr. Ranney had obtained by the use of hot water, and he gave it with the meals.

Dr. R. W. Amidon had had no experience in the use of hot water in purely nervous diseases, but in the treatment of nervous phenomena such as attended certain cases of dyspepsia, anæmia, particularly associated with the rheumatic or gouty diathesis, he had employed it to some extent. He regarded the derivative action of hot water as extremely doubtful. Moreover, Dr. Ranney had said that no beneficial effects were to be expected until six months had elapsed, but according to his experience no counter-irritant or derivative acted as slowly as this.

He believed that water acted mainly on account of its diluent qualities, and especially so when the vascular system was depleted, as it was in many if not most of the class of cases in which beneficial effects had been obtained by its use. That it might act as a tonic, producing its effects slowly, might be explained on the ground of gradual improvement of the powers of assimilation in accordance with well-established chemico-physiological laws.

Dr. L. Putzel had had no experience in the use of hot water, but thought that the experience advanced by the author of the paper proved too much; for it had been stated that hot water was efficacious in cerebral hyperæmia and cerebral anæmia, and if it produced any effect, which was altogether unproven, it could not be beneficial in opposite conditions.

He thought some stress should be laid upon the point made by Dr. Amidon, namely, that therapeutic agents of this kind act quickly. Hot water should act best at first, if Dr. Ranney's theory was correct. Dr. Putzel was unable to see how any agent which acted in this manner could possibly have any effect upon such organic disease of the nervous system as locomotor ataxia, and he should be very much inclined to regard the improvement which Dr. Ranney had reported in these cases as due to the law of coincidence.

Dr. W. R. Birdsall believed that there was considerable efficacy in the use of hot water, as well as cold water. He was not prepared to deny the agency of heat in the use of hot water, and believed that it was one of the principal agents in producing its therapeutical effects. What he had wished to hear from the author of the paper was statistics of a clear character, but unfortunately in all of the cases reported quite a complicated plan of treatment had been adopted, consisting in a combination of agents, nearly all of which had been found more or less beneficial in the treatment of the diseases under consideration. Certainly no use could be made of those cases.

With regard to the use of hot water in the treatment of functional disturbances of the nervous system, there were always so many complicating influences that it would be a long time before we could separate the therapeutical action from the mere diluent action of the water. Still he believed that heat played an important part in producing irritation of the mucous membrane.

Dr. C. L. Dana had used hot water in the treatment of chronic functional nervous diseases, chiefly in hysterical women with symptoms of gastric disturbance, and had been disappointed in the results. Perhaps the failure to obtain benefit was due to the lack of care in its administration, so minutely urged by the reader of the paper.

Many years ago Dr. Wilkes had demonstrated that the best results had been obtained by the use of agents which did not act upon the nervous system specifically, and therefore it was altogether probable that the line of treatment laid down by the author of the paper was likely to prove extremely useful.

Dr. J. L. Corning had used hot water in the treatment of digestive disturbances concomitant with functional diseases of the nervous system, such as neurasthenia, etc., and had obtained good results. He had no theory to offer with regard to the action of the agent, but could not agree with Dr. Ranney that the good results were deferred for six months, for he had seen benefit follow within six weeks or two months.

Dr. John Scott, of San Francisco, first visited the Academy in 1866, when he had the pleasure of listening to a paper and discussion participated in by our honored president. His next visit to the Academy was at this meeting, and he had been querying in his own mind as to how it was the president maintained his perpetual youth. On confidential inquiry, however, he had learned to his intense satisfaction that it had been maintained largely through the agency of hot water. He was not aware when he came to the meeting that the paper was to have any special political significance, but it might be said to have taken such a turn, and as to what its immediate or remote effect would be upon the result of the political canvass was not easy to say; perhaps the paper might be regarded as a political speech in favor of St. John. He had queried also as to what was to become of all of the doctors and the druggists, should the plan of treatment advocated so ably by the author of the paper be carried into full effect.

During the last thirty years he had used hot water for a variety of affections, but chiefly for checking emesis, especially that which occurs after the administration of ether. He had also employed it in the treatment of a large variety of affections, changed somewhat in color to be sure, and more especially in the form known as milk, and he believed that he had obtained equally good results as those which had been presented by Dr. Ranney.

Dr. T. H. Burchard asked the author of the paper, first, if he had seen any serious or permanent injury done to the digestive apparatus by the long-continued use of hot water, and, second, whether he had noticed that the hot-water treatment had developed a predisposition to intestinal and gastric hemorrhages. He had had opportunity to see a large number of patients who had been following this plan of treatment quite faithfully, and in quite a proportion of them he had encountered the permanent digestive disorders alluded to, and also the tendency to the occurrence of internal hemorrhage.

Dr. Ranney, closing the discussion, said he had not seen any cases, either of internal hemorrhage or permanent impairment of the digestive organs, alluded to by Dr. Burchard. He had seen people who had been re-

duced in flesh rapidly by the use of hot water with restricted diet, but this was purposely done, and when the treatment had been discontinued they immediately began to gain in weight.

He thought Dr. Seguin's criticism with reference to the degree of heat was not valid when the water was taken as he had directed—taken in teaspoonful doses as hot as the patient could swallow, less than 110° F. never being used. Dr. Seguin's theory that ice-water would lose heat in its transmission to the stomach, when applied to the use of hot water would increase the heat, and therefore increase the efficacy of the agent.

The effects produced by the agent were as immediate as they could be; sometimes it took six weeks to get marked effects, and sometimes it took six months to get the best effects. Certainly he did not mean to say it required six months to get any effects from the use of hot water.

The double action of the water—that is, the beneficial effects produced in cerebral hyperæmia and also in cerebral anæmia, could be very easily explained on the ground that the tendency of the agent was to restore the vascular apparatus to the normal condition, and therefore it might prove beneficial in either abnormal condition.

So far as his theory concerning the action of the agent was concerned, it might be totally incorrect. He simply advanced it as one which was plausible, and as the one which seemed to him best to explain the action of the agent.

Of course he had no clear statistics to publish. He had simply mentioned a few results, had brought forward a few cases in which he had tried the agent after well-recognized methods of treatment had proven ineffectual. Complete statistics could be obtained only after a more continued employment of the hot water in distinct classes of cases.

HYDROCHLORATE OF COCAINE AS A LOCAL ANÆSTHETIC TO THE CORNEA.

Dr. C. R. Agnew directed the attention of the Academy to the local use of this agent, and demonstrated its anæsthetic action by applying a two per cent. watery solution to the scleral conjunctiva of two persons. Since the publication of the interesting letter of Dr. H. D. Noyes, which appeared in The Medical Record for October 11, 1884, he had employed it in fifteen or sixteen cases, and with results which had been, both to observers and to himself, most satisfactory and astonishing. At the present time he felt that nothing had been given to surgery of greater importance since the introduction of ether. It was yet to be demonstrated whether the agent when dropped into a wound would produce local anæsthesia. He distinctly disavowed any attempt to claim priority in its use in this city, but wished merely to demonstrate its marvellous effects to the Academy.

Dr. Burchard had seen a case of felon in which the finger was immersed in a solution of cocaine, and local anæsthesia was produced so that the patient suffered no pain when the finger was opened with the knife.

Dr. Birdsall spoke of the benumbing effects produced upon mucous membranes by erythroxylon coca.

The President referred to the use of the fluid extract of coca for strengthening the vocal cords and improving the voice.

The Academy then adjourned.

A Society for Psychical Research.—An attempt is being made in Boston to organize a society for psychical research; *i.e.*, for the study of mind-reading, spiritualism, mesmerism, etc. It may not be generally known that a similar society exists in this city, under the modest title of "The Academy of Anthropology."

Midwives in Buffalo, N. Y.—Two-thirds of the obstetrical cases reported in Buffalo, N. Y., are said by Dr. Pryor to be attended by midwives.

Correspondence.

A PLEA FOR THE COUNTRY PRACTITIONER.

To the Editor of The Medical Record.

Sir: In your editorial on "The Importance of Holiday Seasons for Physicians," you state that "the city physician is subjected to causes of ill-health from which his country *confrère* is comparatively exempt;" that "the latter breathes purer air and has invigorating rides over hill and plain," etc. Having had about ten years' experience in such invigorating work, I think I can speak from experience. There are no harder worked physicians on earth than the country doctor, with a large practice, and none that needs vacations more. His long rides expose him to every kind of weather, and there is hardly a storm but what he is caught out in it. The roads in country districts where there are no pikes get almost impassable in rainy winters, and we generally have it very wet every alternate winter here in Central Ohio. I have known the roads to break up and remain so from October until May, not frozen so you could drive a wheeled vehicle a dozen days during the winter—mud often to the horse's knees from fence to fence. The consequence is that we are obliged to ride horseback, a very laborious way, especially if indulged in for five or six months, almost night and day. The fact is, that a great many country doctors find long rides so intensely invigorating that they have to quit, or go to the city in order to get that rest so much needed by the hard-worked practitioner.

It costs but little more to live in the city than the country when we take into consideration the amount that the country doctor pays for his medicine, and the number of horses it requires to ride over a big scope of country. He can't get along with less than two, and to do justice to the horses he needs four more often.

The competition in this part of the country is just as great as in a city. "The country is full of doctors;" every little town has from one to five or six, and they are not all blockheads either, but wide-awake, shrewd men, who understand their business. Country practice is more difficult than city for many reasons. The country physician is known by all, and his every movement is watched and scrutinized and criticised. When he makes a mistake, or a supposed mistake, it is heralded everywhere, and "off comes his head" often. If the city doctor loses a case, it is not known a square off, and it doesn't hurt him. A city doctor can get along with less knowledge, for he is always acquainted with men eminent in their specialties, and he can consult them. In the country the doctor has to practise all the branches of medicine in order to be successful, consequently he has to study hard, as well as work hard, to succeed

The country doctor's social advantages are not to be compared to the city physician's. The latter can have anything in the city suited to his tastes, while in the country it is long, wearisome journeys and irregular sleep and irregular meals. I ask what can be more wearing? If anyone thinks the country doctor has the best end of it, he is very much mistaken. They are the backbone of the profession, and have not gone to the country for lack of knowledge, but on account of an idea that they can start with less money, which is often a mistake.

Columbus, O.

"DEAD TEETH IN THE JAWS."

To the Editor of The Medical Record.

Sir: The report of the cases of otologia occurring in the aural service of Samuel Sexton, M.D., on page 374, current volume, entitled "Pain in the Ears due to Irritation in the Jaws," while it may serve to direct the attention of physicians to make a closer examination of the teeth in all cases of pain in the ears, yet fails to establish the fact that retention of dead (pulpless) teeth in the jaws is a prolific source of aural troubles. A careful examina-

tion of that report fails to disclose an alarming number of dead (pulpless) teeth. Case I. reports: "Lower first and second molars on both sides mere shells." No proof that the pulps were dead. The surgeon who advised extraction of the four (temporary) molars destroyed the masticatory apparatus of the child for at least three years, and in all probability caused the first permanent molars to tip forward, so that the crowns of each will be almost useless during life for mastication; and in addition to the above produced an irregularity of the bicuspids (yet to make their appearance) which will probably render it necessary that one on each side should be extracted in order to afford space for the remaining teeth. Case II. "Both upper wisdom-teeth in a carious state. Both lower wisdom-teeth just (cut?) erupted." The absurdity of the proposition that the wearing of the vulcanite plate increased the irritation in the left ear is too palpable to need comment. Case III. No proof of dead (pulpless) teeth. Case IV. No proof of pulpless teeth. The pain in the ears in the preceding cases was undoubtedly due to exposed or nearly exposed pulps, which any dental surgeon could have relieved, and at the same time saved the teeth alive. Case V. No proof of pulpless teeth. The advice was good. Case VI. No proof of pulpless teeth. From the report it seems that an unnecessary number of teeth were extracted because they were carious! Case VII. No proof of pulpless teeth. Removal of the salivary calculus probably all that was necessary. Case VIII. No proof of pulpless teeth. The erupting wisdom-tooth probable cause of pain in the ear.

The comments of the surgeon in charge are exceedingly entertaining. He first advises the extraction of a vast number of carious (not dead) teeth, and then complains that the wearing of plates (celluloid, vulcanite, etc.) is "an evil of vast proportions." I agree with him in the proposition that a vast deal of ill-advised dentistry is done every day, but this evil is due as much to the ignorance of the surgeon and physician as to the lack of judgment and skill on the part of the dentist. It is no uncommon experience of dental surgeons to find otherwise well-informed medical men deplorably ignorant when speaking of dental anatomy and the diseases of the teeth.

The editorial comments on the report above reviewed are not particularly well-timed. The idea that because an alveolar abscess may be found discharging into the mouth a drop or two of pus every day should be thought a sufficient reason for the extraction of the tooth is not tenable, as it is well known that any alveolar abscess—arising from death of the pulp—can be cured by any competent dental surgeon. I agree most heartily with the editor when he says, "It would seem . . . that perhaps the time is nigh at hand when medical men should be themselves better informed concerning diseases of the mouth and jaws." It is high time. No intelligent dentist could be such an ass as is implied in the paragraph, that he would continue "'treating' dead teeth long after their presence in the jaws has given rise to alveolar abscesses and neuralgias more or less painful." The necessity for "treating" a dead (pulpless) tooth is not well established until the formation of an alveolar abscess. It is presumed that no argument is called for to sustain the proposition that alveolar abscesses should be cured; that nearly exposed pulps in teeth should have a suitable capping interposed between the pulp and the filling to prevent thermal shock; "that all dental surgeons should receive proper and sufficient medical teaching to enable them to prescribe intelligently and to diagnose correctly;" but in the light of present advanced dental knowledge and practice, to have the profession of dental surgery, whose history contains a list of names not less known in the world of science than those of any other honorable profession—Owen, Czermak, James, Mayital, Wells, Harris, Garrettson, Wedl, Bell, and hosts of others whose names are indissolubly connected with the science and practice of dentistry—alluded to as "individuals whose limited knowledge of medicine," etc., by the editor of an enlightened, progressive, and professedly liberal medical journal, is rather straining at the gnat to swallow a camel. This present "individual" protests against such editorials as undignified, unjust, and uncalled for. Respectfully yours,

A. W. Harlan, M.D., D.D.S.,
Prof. Dental Surgery
Coll. Physicians and Surgeons of Chicago.
70 Dearborn Street, Chicago.

THE FEEDING OF INFANTS WITH COWS' MILK.

To the Editor of The Medical Record.

Sir: The Medical Record of September 13th contains an article by Dr. John Binnie upon artificial feeding of infants by means of cows' milk. I am an earnest advocate of this article as a substitute for mother's milk, and agree in the main with the suggestions advanced in the author's paper. But I am of the opinion that too much stress is laid upon the necessity of employing milk from one and the same cow. If the article is good, I maintain that its effect upon the infant is in nowise deleterious, whether it be procured from one or many cows. The great desideratum is that it be as pure as possible It is my experience that change, always keeping in view the purity of the milk, produces no harmful results. To exemplify: A few years ago I had under daily observation an infant six months old, travelling with its parents through the various large cities and countries of Central Europe. I lay special stress upon *cities*, because milk is supposed to be more inferior there than in the country. A month was consumed in the journey, this latter being interrupted by rests of one to seven days' duration. Upon arrival at these places the best milk that could be procured was ordered, and notwithstanding this constant change of milk obtained from different cows of the same nationality, and even the immediate substitution of that of another State, the infant enjoyed most perfect health.

I coincide with Dr. Binnie in respect to the causes which produce harmful effects, with the exception of the one cited above. *Change* is the most insignificant of the causes of failure.

The predominating cause of evil results from bottle-feeding is the want of cleanliness. Not only should the utensils be perfectly clean, but they should be of the simplest possible character. All feeding-bottles with long rubber attachments should be condemned. While these lighten the labor of the attendant, they are a constant menace to the child's health inasmuch as they become a focus of disorders, the walls of the tubes affording a depot for the particles of milk; and notwithstanding they may be rinsed, brushed out, and allowed to remain in water, they will in a short time be found coated, this coating fermenting the milk passing through them. The simple nipples, then, are the safest. In employing these several should be kept on hand, that those not in use might stand always in cold clean water. When they are found to be coated, they should be discarded. With respect to the bottles, it is better to have also several of these, those not in use being filled with water. They should frequently be cleansed with soda and hot water.

Feeding should be limited to every two hours in the very young child. Later, the time may be extended to every third hour. In the interval, if the infant cries, I advise a little pure or slightly sweetened water. During the early months the proportion of milk should be three parts to one of warm water, the former uncooked. The amount of nourishment must be gauged to the little one's capabilities to retain it. The flask should be removed from the child's mouth immediately after it is emptied, in order that air may not be sucked into the stomach. During the process of feeding the nipple must be maintained full for the same reason. I have found that a teaspoonful of lime-water added to each bottle of milk is indicated when there is much vomiting after feeding, or

when the bowels are "bad." When there is constipation, a teaspoonful of mag. sulph. mixed with the milk is called for. In preparing this it is better to add the milk to it slowly in a vessel other than the bottle until the powder is entirely dissolved, when it is poured into the flask. If it is not so treated the nipple is often clogged up.

At no age under two years do I permit table food to be eaten. I confine the feeding to the bottle, crackers, and bread with very little butter. I have seen children thus fed pass over the entire period without experiencing a day's sickness, excepting the eruption of the teeth and vaccination. I have never known them to suffer even with colic.

I am opposed to all species of artificial food as a substitute for cows' milk, believing that the latter is the nearest approach to mother's milk.

In conclusion, I would say that when the mother is from any cause unable or unwilling to nurse her infant, I unhesitatingly elect bottle-feeding, giving it preference to the wet-nurse, believing as I do that the child will thrive as well, and will run fewer risks than if the latter method be adopted. A child fed as I have indicated has every chance of living, and will develop as well as one fed upon its mother's milk or one wet-nursed. That it demands more care and calls for more attention there is no question. Bottle-feeding should be intrusted to careful hands only, and should be supervised by the medical attendant.

ETIENNE C. VIDAL, M.D.

SHALL ARMY SURGEONS PRACTISE OUTSIDE THEIR POSTS?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In my last letter, regarding the practice of army surgeons among civilians, I stated that Dr. Stanton represented the matter in an unfair light, and his late arguments do not alter my views. It seems difficult to understand why an army surgeon should not have a perfect right to practise his profession among civilians, if they choose to employ him, and if it does not interfere with the duties of a medical officer.

The point advanced by Dr. Stanton, that the law officers of the Government are not allowed to give legal advice to the public, is not well taken. It would seriously interfere with the proper administration of justice if judges and prosecuting attorneys were allowed to engage in private practice, but no ill effects can arise by giving army surgeons the privilege of extending their services to civilians. A man who enters the military or civil service of the Government does by no means surrender the rights and privileges of a citizen, and no reason or justice could possibly be found in any law, regulation, or order, which would prevent a physician in the employ of the Government from using his knowledge and skill, during his leisure hours, not only for the benefit of his fellow-men, but also for the purpose of increasing his income.

In other branches of the public service, either municipal, State or federal, the attachés engage in outside work, and it is quite common to see Government clerks augment their income by performing clerical work for private parties during their leisure time. If Dr. Stanton's arguments hold good, why is it that it never occurred to our lawyers, or other professional or business men, that it is improper for Representatives and Senators to give legal advice, or to continue the practice of their profession, or attend to other business, while they occupy seats in Congress and are paid a fixed salary? Why does not Dr. Stanton object to the outside practice of physicians and surgeons of municipal or other government hospitals, medical officers of boards of health, police surgeons and harbor physicians, not to mention the medical officers of the navy, the surgeons of the Marine Hospital service, pension surgeons, and many others? Most of them draw fixed salaries, "in part paid for by the very physicians they compete with," and many of these positions are as permanent as those held by army surgeons, and are the means of bringing the holders a large private practice, which medical officers of the army can never hope to gain.

As Dr. Stanton says, what will apply to one branch of the public service must apply to all others. According to his views it would be sound logic to prevent all public office-holders from engaging in private pursuits during their leisure hours. To allow them to occupy their spare time for any laudable and honorable purpose, with a view of adding a few dollars to their fixed salaries, would open a way for "unfair and unjust competition" with others, who have not "an assured and regular income outside of their practice," trade, or profession.

I still claim that much of the outside work of army surgeons is done with a view of increasing their knowledge, and I have found, as a general rule, that citizens often apply to army surgeons for medical advice, for which they never expect to pay, because they seem to be impressed with Dr. Stanton's views, "that it is not proper for them (the surgeons) to receive fees for so doing." Much of the work of military surgeons among civilians is a work of charity, and citizens in need of medical aid never apply in vain to army medical officers for assistance. The argument that it would be ungracious to prohibit a medical officer from extending relief to civilians is by no means "unmitigated bosh," and I recall more than one case, which happened not only on frontier posts, but also in large cities, with no "dearth of local physicians," where such restrictions would have been followed by most serious results.

But it is also true that at a few military posts some of the better class of people, living in the vicinity, consult the army surgeon, and, like all decent people, pay for the services rendered. The incomes of army surgeons are by no means brilliant, and since most of them have families to support and children to educate, it appears only praiseworthy if they try to increase their income by engaging in private practice.

Medical officers of the army are not very liable, as a general rule, to come in active competition with local physicians. At the majority of posts their official duties occupy most of their time, and even if such is not the case, they suffer from the disadvantage that they are almost strangers in the vicinity of their stations. Army surgeons are usually changed every few years, and people are not in the habit of changing their old and tried physician, if he is what he should be, a friend, an adviser, and a man well versed in the art of healing.

I have occupied much of the valuable space of your paper, but I shall not ask your indulgence in the future, and if additional replies should be required, I beg to transfer the matter to abler hands.

Very respectfully, CADUCEUS.

CHLOROFORM A DANGEROUS REMEDY FOR TAPE-WORM.—Dr. J. W. Carhart, of Tampasas, Tex., writes that on August 10th he administered the following prescription for tape-worm, as recommended by Dr. J. G. Brooks:

℞. Chloroform,
Ext. filic. mas. fl. ..... āā ʒ ij.
Emul. ol. ricini. ..... f ʒ iij.

M. Sig.—One dose after twenty-four hours' fast.

The patient, a lady, very soon after taking the dose, passed through the excitement stage of anæsthesia, then suffered from nausea and vomiting. She did not get over the bad symptoms until next day. No tape-worm was discharged, though the patient had been passing fragments for some time. Dr. Carhart has had good results with Tanret's pelletierine, and is done with chloroform.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 12 *to October* 18, 1884.

NORRIS, BASIL, Lieutenant-Colonel and Surgeon. Relieved from duty as Attendant Surgeon, Washington, D. C., and ordered for duty as Medical Director Division of the Pacific and Department of California, relieving Surgeon E. I. Baily. Colonel Baily, on being relieved, will assume the duties of Attendant Surgeon at San Francisco, Cal.

SPENCER, WILLIAM C., Major and Surgeon. From Department of Dakota to Department of the East.

GODDARD, CHARLES E., Major and Surgeon. To be relieved from duty at Jefferson Barracks, Mo., and to report for duty in Department of Dakota.

MCCLELLAN, ELY, Major and Surgeon. From Department of the East to duty at Cavalry Depot, Jefferson Barracks, Mo. S. O. 242, A. G. O., October 15, 1884.

MCKEE, JAMES C., Major and Surgeon. Granted leave of absence for one month, with permission to apply at Division Headquarters for one month's extension. S. O. 149, par. 1, Department of Colorado, October 3, 1884.

WOLVERTON, W. D., Major and Surgeon. Granted one month's leave of absence, to take effect when his services can be spared by his Post Commander. S. O. 211, par. 4, Department of the East, October 16, 1884.

HAVARD, VALERY, Captain and Assistant Surgeon. Assigned to temporary duty at Fort Schuyler, New York Harbor, N. Y. S. O. 211, par. 2, Department of the East, October 16, 1884.

PORTER, J. Y., Captain and Assistant Surgeon. Granted leave of absence for one month, on surgeon's certificate of disability, with permission to leave the limits of the department. S. O. 138, par. 3, Headquarters Department of Texas, October 9, 1884. Confirms telegraphic order of same date.

Official List of Changes in the Medical Corps of the U. S. Navy, during the week ending October 18, 1884.

BRUSH, GEO. R., Surgeon. To temporary duty at the Naval Laboratory. October 11, 1884.

BURBANK, CHAS. H., Medical Inspector. Detached from the Brooklyn, and placed on waiting orders. October 15, 1884.

CLARK, JOHN H., Surgeon. Detached from the Lackawanna, and detailed as Fleet Surgeon of the Pacific Station. October 17, 1884.

COOKE, GEORGE H., Surgeon. To the Lackawanna. October 17, 1884.

EDGAR, JOHN M., Passed Assistant Surgeon. To the receiving ship Franklin. October 11, 1884.

HUDSON, A., Medical Inspector. Detached from the Lancaster, and placed on waiting orders. October 14, 1884.

HUGG, JOSEPH, Surgeon. Placed on waiting orders. October 13, 1884.

LOVERING, P. A., Passed Assistant Surgeon. Detached from the Lackawanna, and placed on waiting orders. October 17, 1884.

MARSTELLER, E. H., Passed Assistant Surgeon. Detached from the Monongahela, and ordered to the Lackawanna. October 17, 1884.

MARTIN, WILLIAM, Assistant Surgeon. Detached from the Passaic, and placed on waiting orders. October 14, 1884.

MARTIN, H. M., Passed Assistant Surgeon. Detached from the Brooklyn, and placed on waiting orders.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 18, 1884:

ELECTRICITY AS AN AGENT IN PROMOTING THE ABSORPTION OF PLEURITIC EFFUSION.—Dr. W. T. Baird, of Albany, Texas, writes us a letter commenting upon Dr. Guiseppe Manzini's views on the use of electricity in pleuritic effusions. Dr. Baird thinks that electricity is not necessarily an irritant, but may act as a powerful sedative, and it is not therefore contra-indicated in the inflammatory stage of pleurisy. He argues also that it is not by electrization and stimulation of the respiratory muscles that electricity causes absorption, but by its vaso-motor stimulation and general tonic effects. General as well as local faradization would be a more successful method in treating these effusions.

THE MOTOR POWER OF THE HUMAN BODY.—Dr. Marey, of Paris, read a paper on this subject at the International Congress of Hygiene, in which he described the ingenious manner in which he had succeeded in measuring the motive power of the human body in its every movement. Planks, with india-rubber coils underneath, recorded, by expelling the air they contained, the exact pressure of the foot. The motions were measured; and photographs, taken in one-thousandth of a second, recorded every attitude during a leap, and where and when the effort was greatest. By such studies, M. Marey had been able to prove that something was gained in the power of walking, in quickening the step from forty to seventy-five steps per minute. But the latter figure was the extreme limit; with a greater number of steps power would only be lost instead of gained.

THE EXPERIENCES OF A HAY-FEVER PATIENT.—A writer in the *Times* says: "I have had 'hay-fever' for nearly twenty years, and I have visited many of the places set down in the association pamphlet as exempt. The best locality I have so far found is the Adirondack Mountains. At Keene Valley, Lake Placid, and a hundred other places within them, there is sure relief. But one must be sure to go into the mountains away from the railroad. I have tried the White Mountains for four years. They are excellent, but not always thoroughly exempt, for an overheating of the body will often bring on a bad attack of sneezing, and in rainy weather one notices a slight difficulty in breathing. In the Adirondacks there are places so exempt that one can do anything and not know that he ever had 'hay fever.' I have tried many of the places mentioned on Lake Superior, and have found exemption in them all. Neither have I suffered in St. Paul or Minneapolis to any noticeable extent, or at Lake Minnetonka. Fire Island, the Isles of Shoals, and others similarly situated near the land, are not so good as the primitive mountains. They relieve the disease wonderfully at all times, but it is only when the wind blows from the sea that they give perfect exemption."

CONTRIBUTIONS TO THE ANATOMY OF THE LEMNISCUS.

WITH REMARKS ON CENTRIPETAL CONDUCTING TRACTS IN THE BRAIN.

BY E. C. SPITZKA, M.D.,

PROFESSOR OF NEURO-ANATOMY AND PHYSIOLOGY IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

(Continued from page 451.)

IV.

V.—RELATIONS OF THE LEMNISCUS PROPER TO THE INTERNAL CAPSULE.

WITHOUT entering into a special discussion of that part of the lemniscus which occupies the olivary territory in lower levels, and in higher ones becomes fused with that portion of the interolivary tract which with it constitutes the main part of the lemniscus, let us proceed to consider its relations in higher (cephalic) levels, where the greatest obscurity prevails.

The gross appearances indicate a transition of a part of the lemniscus, which reaches higher (more cephalic) levels than the post-optic lobes, into the internal capsule. To what extent there is interruption by thalamic gray matter is uncertain, but the gross appearances alluded to appear to correctly match the real relations.

In levels slightly caudad of the one in the figure, where the thalamus is struck in its free portion, a clear triangular field is seen (6), which is an inverted and magnified reproduction of the lemniscus triangle; it is a fasciculus of the corona radiata. On passing cephalad, a part of the lemniscus runs into a field occupying the place of 6. It would appear as if the thalamus intruded its substance, so that to reach its double the lemniscus has to break through. The more plausible explanation seems to be that the fasciculus bends round from within outward, with the convexity cephalo-mesad, leaving the gray streak latero-caudad, so that what was internal and posterior (meso-caudal) in the lemniscus, became external and anterior (ecto-cephalic) in the capsule, and what was external in the lemniscus became internal in the field replacing 6. The curve in field 27 of Fig. 12 indicates such a relation, while the course of the tract in the specimen from which Fig. 11 was drawn, is of similar import, but indicates also a laminated dispersion through gray matter.

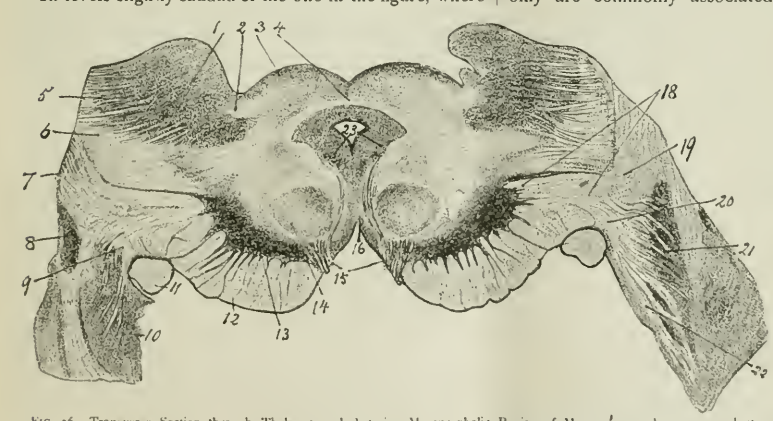

FIG. 16.—Transverse Section through Thalamic and Anterior Mesencephalic Region of Man. ½, numbers in aqueduct, pointers on nuclei of third pair; 3, anterior pair of corpora quadrigemina; 6, field of optic radiations of Gratiolet, chiefly derived from external geniculate body and optic tract; it is traversed and perhaps joined (?) by thalamic radiations; 7, 18, 19, passage of Gratiolet's fasciculus into the capsule, in part to temporal lobe; 20, 21, 21, similar passage of pes fibres into and through the posterior serrations of the lenticular nucleus (21); 12, pes; 13, substantia nigra; 14, tegmental nucleus; 15, roots of third pair. It was neglected to designate the lemniscus field; comparison with Fig. 14, L, will aid in its identification; it occupies the triangular field included between the upper lateral angle of the aqueduct gray, intrudes one end between the outer aspect of the tegmental nucleus and the substantia nigra, and detaches its third corner part toward the field 6; the mesal demarcation is not as distinct in this level as in one of those to be described.

Forel[1] could never discover a transition of lemniscus fibres into the thalamus, a small part he traces to the corpus mammillare, but the major part (*Haupt-theil*) becomes lost in a confused medley of finely broken up gray and white substance in the latitude of Meynert's bundle in the dog, while in man the gray substance is wanting, the lemniscus remains more compact, and as I have not been able to confirm from a study of specimens stained in fuchsin,[2] its fibres appear matted together like felt-work.[3] I am unable to come to any conclusion as to the relation between the post-brachium and the lemniscus layer alleged by Forel. The direction of his sections is about the most unfortunate to have selected, as the majority of tracts are divided obliquely in them. His employment of transverse sections (Meynert-Stilling's plane) in the dog, possibly accounts for his finding the relations of many tracts clearer in that animal than in man. Our conceptions as to direction and space in anatomy are commonly associated with the great body planes, and to this simple tradition of topography Forel's sections do great violence.

I think that by describing the relations of the lemniscus main portion (*Haupt-theil*—Forel) in three successive levels of the Meynert-Stilling plane, I may make myself better understood than by proceeding immediately to consider the course of the fasciculus as such.

First level: Through the anteriormost twelfth of the pons, and the middle of the post-optic lobes (post pair, *C pp*, quadrigemina), the main lemniscus and the detachment to the post-optic lobes are altogether, the pedo-lemniscal fasciculus nearly continuous,[4] covering Soemmering's substance dorsally. The mesal two-fifths of this united area follows the ventral face of Wernekinck's commissure, being separated from it by a gray

[1] Archiv für Psychiatrie, vii., pp. 431–433.

[2] I am indebted to Dr. Starr for this staining reagent; its future usefulness think will be made most evident in this particular region.

[3] Fibres can be traced for more than the width of the field outward; other fibre noticed obliquely divided in the interstices of the intervening bundles cannot b confounded with them.

[4] A small detachment of Soemmering's substance intervenes.

intercalation. In my case of secondary degeneration the outer portion was shrunken and degenerated, only a small area of the part, a third the half diameter from the raphe, escaping.[1]

Second level: Through the anterior pair, and the pedunculi cerebri, at the level below the emergence of the third pair, striking at the same time the external geniculata. Main lemniscus, separated through substantia nigra from the pedo-lemniscal tract by a large interval. It occupies a nearly mortar-shaped area, the mortar being supposed to be inclined dorso-laterad. Its base rests half on the lateral sector of the area of the *tegmenta brachium*, the other half fades away into the dorso-mesal face of the lateral half of the substancia nigra. The mesal end of the top of the mortar is represented by the end of the lemniscus field, the ectal end by fibres which begin to field through the gray matter between the lemniscus and pulvinar. Most of these fasciculi may be traced a considerable distance toward the field which replaces 6 of Fig. 16 in higher levels. In lower levels where this fielding off detachment is not marked, the lemniscus resembles the horns of a Cape buffalo, attached to the field of the *tegmenta brachium*, just as the latter are attached to the bulbous enlargements of the Cape buffalo's forehead.[2] Degeneration in my case occupied the ectal half of the mortar as well as the process directed toward the substantia nigra. The part directed to the tegmental nucleus, and which is mixed with fibres of the tegmentum proper was unaffected.

Third level: The lemniscus area described under two becomes smaller and smaller as the fielding off continues; finally direct fasciculi can be traced into the internal capsule. These were degenerated in my case, where detailed examination showed total destruction of the middle (main) part of the lemniscus tract. The course of the bundle which the dying out lemniscus sends to the capsule, is first directly ectad, and into the lower part of the field continuous with 6; it does not join the latter, but changing in direction dorsad leaves the level of the section. The field which these lemniscus fibres appear to occupy in the capsule is situated on the border of the inward and downward slope of the thalamus, in a level slightly anterior to that of figure 16; to accommodate it, the triangular field 6, is moved laterad and more dorsad. A direct continuity to this field is not demonstrable, but as it appears with the disappearance of the lemniscus the course of the fibres is in that direction, and no other adequate source[3] can be discovered, it is reasonable to connect them, provisionally at least. As already stated, fibres can be traced from the lemniscus field to the borders of this one, and above this level the corresponding part of the lemniscus can no longer be identified. Defibrillation supports this view with all the weight which may be attributed to its uncertain evidence, and indicates that the fasciculus in which it runs occupies the course represented in the tract 27 of Fig. 12. In my case of secondary degeneration, the latter occupied a field dorsad of the radiations from the tegmental nucleus to the capsule, and up to date has not been traced further.

The relations of the internal capsule at this point are very complex, but interesting. The outermost fibres of the *pes* are the first of this bundle to enter it, as we pass caudo-cephalad. In transverse sections a bundle is seen (18, Fig. 16), which is repeated in a number of levels. In the lowest it represents Gratiolet's fasciculus,[4] which unites the occipito-temporal lobe to the cerebellum; on the level of the body of Luys, the corresponding bundle connects the body of Luys with the inner articuli of the lenticular nucleus.[1] This latter connection is one of the most satisfactory demonstrations of the section method. It is in the field 19, which with the elimination of the field 6 comes in contact with the zonal stratum of the thalamus, that the outer part of the main lemniscus tract appears to run.

I am unable to contribute anything to the knowledge of that part of the lemniscus which Flechsig traces to the *ansa lenticularis*, the analysis of the material at my disposal not having been completed. It would be a remarkable coincidence if, as is not unlikely, the lemnisco-pedal tract, after temporary deflection to the pes pedunculi, took the same course. Thus would the two divisions of the stratum intermedium become reunited.

VI.—A Note Regarding the Column of Goll.

On reviewing the subject of the fœtal and post-fœtal development of nerve-tracts, I found that many of the corrections since made of Flechsig's representation of the course of Goll's columns, in his first treatise, where he leaves them undesignated in lower dorsal levels, and represents them as a semi-oval area on either side of the posterior fissure of the cord, could have been made by a more extensive study of embryonic material. There is really no difficulty in recognizing this tract, in perfectly fresh cords. Through the courtesy of Dr. Jean F. Chauveau, I had the opportunity of examining the cord of a foetus (forty-one centimetres from vertex to heel), and found that the tract of Goll is triangular with a pointed apex, directed toward the point of entry of the posterior roots; it failed to reach the dorsal periphery of the cord, except near the fissure. It exactly reproduced the extent of secondary degeneration noted by recent German writers, and the mesal degeneration in a case of locomotor ataxia in a patient of Dr. McBride's, in whom the root zones of the lumbar enlargement and lower dorsal regions alone were involved, the secondary change in the columns of Goll having evidently advanced only up their lower (caudal) portions. In the fœtus above referred to the right crossed pyramid tract was present in the lumbar cord in its lower levels, while the left was absent. Correspondingly the right tract extended farther forward on the right side in the cervical region, sending a spur between the two divisions of the anterior part of the lateral column. Evidently this is in connection with dextral preference, for there was no compensatory development of the uncrossed tract.

Although the columns of Goll were still gray in this fœtus, the stratum interolivare was in part distinctly white, there was a whitish field dorsad of the ideal prolongation laterally of the substantia nigra, and this field extended into the internal articuli of the lenticular nucleus. I am becoming more and more convinced from the contradictory nature of these findings that absolute reliance cannot be placed upon the apparent continuity of myelinic development. In this case, careful analysis showed that the white matter in the lenticular nucleus was derived from a belt of white fibres surrounding the body of Luys. The converse of Flechsig's proposition, that nerve-tracts which do not develop in chronological accord do not appertain to the same system, has already been shown to be erroneous by Forel.

VII.—The Relations of the Sensory Tracts and the Trigeminus Roots.

The cases of lesion of the pons and oblongata, while indicating that below the exit of the trigeminus nerve the anæsthesia of the face is on the side of the lesion, which was the case in a tumor of the pons (caudal half) and oblongata, last autopsied by myself, are too few, and involve too many other factors to permit of the unreserved acceptation of Starr's conclusion (*loc. cit.*, page 55): that a lesion in the cephalic part of the trigeminal area in the pons will always cause contra-lateral anæsthesia, *as stated*

[1] The lemnisco-pedal tract was entirely healthy. On the normal side a bundle in the plane of the section, ran *in* the substantia nigra from the lemnisco-pedal region to the outer fifth of the main lemniscus, joining it by intrusion and defasciculatioo.

[2] This *simile* may be made for other systems in the mesencephalon, there are three concentric repetitions of a similar arrangement, one of these being the post. long. fasc. of the tegmentum.

[3] The post-brachium is not extensive enough to account for the formation of this field, if, as Forel's statement suggests, the two be confounded.

[4] Even in sections the superficial examiner is misled into suspecting a relation to the optic tract; hence Stilling the younger may have erred in describing such a connection, as he discovered it by the faulty defibrillation method.

[1] I have found four lenticular *articuli* more often than three, and in one case a fifth distinctly marked.

by him. A lesion might indeed occur in this part of the pons, involving the trigeminus roots—descending of the same level, or ascending—previous to their escape from the brain axis, or their union in the great sensory root, and naturally would result in anæsthesia of the same side throughout if direct descending roots existed.

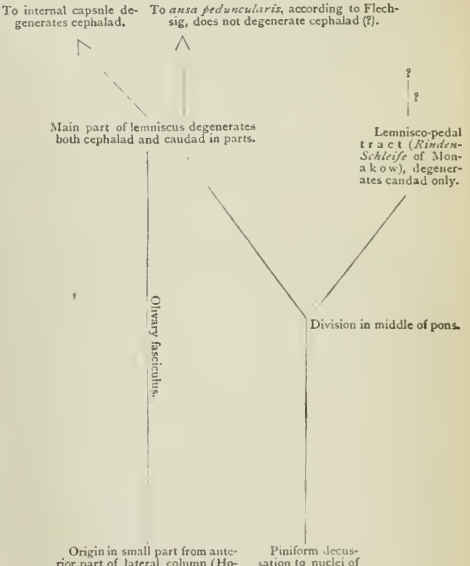
That there is a decussation for certain of the roots of the sensory division of the trigeminus, has been a familiar fact since Meynert's day. Of this nature is probably the great raphe root (Fig. 15, 5r), and a beautiful set of fasciculi, which decussate in the gray matter of the ponto-crural region of the dog, in the immediate continuation cephalad of Wernekinck's commissure (x of the tegmenta brachium). These fasciculi run from a field which corresponds to 14 of Fig. 10 (not necessarily connected with it), decussate in the gray matter to the opposite side, where in a beautiful sweep they reach the exit level of the fifth pair. It, with the raphe root, embodies probably the decussated connection of the trigeminus with the higher centres which Starr had in mind. If the latter's theorem is correctly understood by the writer, it implies that the area of the cephalic part of the pons, homologous with the root region of the caudal half—for that lies in the outer third of the reticular formation—contains a centripetal tract derived from the opposite trigeminus nerve. For this theorem there is thus far no anatomical support, and not even a hypothetical tract, while, as stated, the cases cited are too few and indecisive, although the general proposition that somewhere between the capsule and the nerve-root a decussation must take place is well based on clinical grounds, and has not been contradicted since Wernicke first asserted it. The raphe root of Meynert, and the strands discovered by me in the dog and ape, cannot be traced to the capsule, and it is a great question when the further course of these bundles will be determined, as small focal lesions of the involved districts are among the rarest occurrences in cerebral pathology.[1]

It is nowhere explicitly stated by Starr that he considered the descending (mesencephalic) root of the trigeminus in this theorem, although he speaks of its junction with the ascending root as the spot which separates the area of homo-lateral and contra-lateral facial hemianæsthesia. If he considered the root, ordinarily so called a sensory root, he would—as it remains on the same side throughout, from its origin in the vesicular cells—have to except so much of the trigeminal distribution as is provided for by that nerve-root. Forel, and Wernicke agrees with him, traces this root into the motor division of the trigeminus, so that if his view is accepted, the above exception need not be made. Wernicke also traces à decussated origin from the substantia ferruginea (locus cœruleus), which receives a contribution from the raphe root, and, after decussation, corresponds to what I term the raphe root. To affect this tract, the lesion would have to be nearer the lateral ventricular angle than Starr indicates, inasmuch as the outer third of the reticular field does not include this tract.[2]

Wernicke calls attention to the dilemma that either the descending decussated root embodies all tactile and pain tracts of the trigeminus, or that some other undifferentiated part of the area destroyed by the tumor was in connection with the lower root. I believe only the latter alternative can be seriously considered, and Starr's explanation is in this direction, though it fails to accommodate itself to all the facts of the case, besides having as yet but a very problematical anatomical basis. He concludes, namely, that the central tract for the trigeminus runs in the outer part of the tegmentum. It may in part; but the only cases which permit of a conclusion, as far as they go, antagonize this view. Both cases are cited by Wernicke. First,[1] hemorrhage in the *lower* part of the left crus: right facial and extremity hemianæsthesia, left oculo-motor paralysis, right facial and extremity paralysis. Second,[2] pea-sized cyst in *inner* part of left crus, enclosing the third nerve of that side and extending to the lamina perforata posterior: left oculo-motor paralysis; right facial, hypoglossal, and extremity paralysis; right-sided diminution of sensibility, including the face. With connected "serous" softening of the contiguous right crus, right oculo-motor paralysis supervened later. From these cases it is to be inferred that the trigeminus and extremity sensory tract travel in that region of the crus which is traversed by the oculo-motor nerve—in fact, the tracts which run in the inner (and outer) confines of the tegmental nucleus, corresponding thus to the course of the decussated fasciculi found by me in the dog, to v. Monakow's Rinden-schleife, and to Wernicke's lemnisco-pedal bundle. As the anæsthesia in none of these cases was complete, we must conclude that there may be other tracts, and these may run as Starr indicates, but evidence does not point exclusively in that direction.

VIII.—Conclusions and Some General Observations.

The lemniscus layer is not—as Flechsig claims—divisible into a larger tract which degenerates in the descending direction, and a smaller tract which "does not degenerate for long distances in the descending direction."



To internal capsule degenerates cephalad.
To *ansa peduncularis*, according to Flechsig, does not degenerate cephalad (?).
? ?
Main part of lemniscus degenerates both cephalad and caudad in parts.
Lemnisco-pedal tract (*Rinden-Schleife* of Monakow), degenerates caudad only.
Olivary fasciculus.
Division in middle of pons.
Origin in small part from anterior part of lateral column (Homén's case), chief origin not definitely determined, but possibly from posterior colnmns.
Piniform decussation to nuclei of Goll and Burdach.

The degeneration of Flechsig's larger portion, as in Homén's case, is both ascending and descending, and in that case the impulse to descending degeneration was not sufficient to carry more than a small part near the periphery of the anterior third of the lateral column below the olives. On the other hand, the more compact tract—that is, the interolivary portion—does degenerate in the descending degeneration for its entire (known) anatomical extent. This part is not in "immediate juxtaposition" to the great olives, if by "great olives" the ganglionic part is meant; in the upper quarter of the

[1] I observed in 1877 an oval hemorrhage, destroying the raphe above the level of the raphe root, in a paretic dement, at the same time there was an enormous ventricular hemorrhage and a meningeal extravasation, destroying any value the case might otherwise have had.

[2] Wernicke announced the separation of the trigeminus sensory and the extremity sensory tracts (p. 527, Archiv f. Psychiatrie, vii.) seven years before, and also stated that sensory tracts for the latter remained on the same side for a further extent. He also considers all possible explanations and objections to them that have since been made, in connection with the symptoms reported, in the admirable paper cited.

oblongata it touches the olivary "halo," in the middle olivary levels the inner accessory olive (Fig. 4), while in the lower levels a large mass of fibres (Fig. 3) interposes; this latter is the "Vorderstrangsrest," or remnant of the anterior column.

The stratum interolivare (intermedium), while not the largest, is the most distinct of the lemniscus fasciculi; it detaches two divisions, a larger to the main lemniscus, a smaller constitutes the lemnisco-pedal tract, which latter is a constant feature in the higher mammalia.

Ascending degeneration in the case of a lesion affecting the main part of the lemniscus is partial, as far as it can be traced (in my case), destroying only the outer part of the field in the thalamus region.[1]

The diagram on the preceding page illustrates the relation of these different parts.

Since in Starr's case the lemnisco-pedal division of the interolivary stratum was absent, and this absence was connected with absence of the hemispheres, and as the same (?) tract was degenerated in Monakow's experimental ablation of the cortex, and can be traced by direct anatomical methods (dog), it is to be left an open question whether the interolivary tract does not include fibres having centrifugal functions.[2]

One of the reasons for regarding the interolivary stratum as a muscular-sense tract, is that this is the only sense which can be allowed to decussate from the posterior nuclei in such fashion as this stratum does, if Brown-Séquard's dictum continues to bear the interpretation it did up to the time of Ferrier's experiment. It is, however, questionable whether it is the sole tract for impressions involved in the mechanism of co-ordination! There is a singular unanimity in the description of the kind of ataxia found with lesions of this tract, when alone involved it relates to manipulation, and not to equilibrium. The latter I still believe to be a function which utilizes the paths of the posterior cerebellar peduncle and the vestibular branch of the auditory nerve.

As connected with this question, I would endorse the exclusion of the restiform column from any participation in the conveyance of pain and temperature sensibility made by Starr; this is almost a self-evident proposition. In concluding that the direct myelo-cerebellar tract may set up reflex vegetative acts, the same writer advances a suggestion in conflict with Flechsig's statement to be referred to. Visceral sensations are not unconnected with the unconscious maintenance of the equilibrium, and hence the distribution of the columns of Clarke does not appear opposed to the view that they conduct centripetal impulses regulating the equilibrium. It would be singular, if the cerebellum were a visceral reflex centre, that there should be so little uniformity in its development in connection with the uniformity in visceral functions of all the mammalia, and no harmony between the development of any portion of the cerebellum and the greater or lesser development of the columns of Clarke adduced to support this theory. The association of visceral lesions with cerebellar disease and experimental lesion of the restiform column is, however, a noteworthy fact, and one which seems to necessitate some such explanation as the one suggested, so that the direct cerebellar tract would have to be regarded in part as centripetal (visceral equilibrium impressions) and in part as a centrifugal tract, unless the visceral reflexes be considered as travelling in a different channel from the one carrying the unconscious impressions which determine them. Flechsig[3] concludes that the direct myelo-cerebellar tract conducts in a centripetal direction, and traces it to the cerebellar cortex; later, in the same treatise (p. 42), he cautions against the adoption of the view that exclusively centripetal conduction occurs in the direct myelo-cerebellar tract on account of the connection of the columns of Clarke with the anterior gray horns. May this not indicate an independent reflex arch?

The evidence of passive (non-irritative) lesion of the cerebellum is to the effect that it is not essential to the proper conduction of the visceral functions, not more so than the cerebral hemispheres. The argument contained in the following: "It is a noticeable fact that these symptoms of cerebellar disease (indigestion, vomiting of a peculiar kind, obstinate constipation, polyuria, albuminuria) *unlike* the ataxia, are not produced by lesions of the vermiform lobe *alone*, but occur when the cerebellar hemispheres are the seat of lesions, such as abscess and softening from embolism and thrombosis, which neither increase the intracranial pressure nor affect in any way directly the floor of the fourth ventricle and the pneumogastic centres there or in the flocculus,"[1] takes no account of the fact that Flechsig's method teaches that the direct cerebellar tract connects with the neighborhood of the vermiform lobe (Mittelstück) as contrasted with the lateral parts; or if it does take this into account, must assume an irritative influence by transmission from part to part. Without venturing to pronounce adversely to this theory, I offer the above considerations, leaving it to investigations I am at present concerned with, to contribute further facts to this interesting question.[2]

As the posterior columns are small in the porpoise and inadequate to the formation of the restiform, it is to be assumed that the direct myelo-cerebellar tract is very large in this animal. This tract is connected with the columns of Clarke, whose extent, in the cord, corresponds closely to the extent of those body segments in which the great viscera are collected. In the porpoise, as in all the cetacea and the phocidæ, the visceral cavities are unusually large, and the viscera themselves more complicated than in related animal groups. The cells of the columns of Clarke resemble in shape those of nerve

[1] Over a year ago Hitzig announced before the German alienists and neurologists that he had observed descending degeneration of the lemniscus in a case of lesion in the crural region. His promised detailed publication has not yet become accessible to me.

[2] There is this difficulty about the explanation, if arrest of development is instituted early enough even centripetal tracts are involved by atrophy of the station *to* which they go.

[3] Plan of the Human Brain, p. 24. I cannot agree with Flechsig in the surmise expressed in his sequel, that the correspondence of the size of the olives in the animal scale harmonizes with that of the dentated nuclei, or that both depend for their common developmental grade on the lenticular nucleus or cerebellar cortex. Flechsig himself adds a query to this guess. The fact is that in a series of animals, beginning with the marsupial carnivora (opossum), then passing through some rodentia to the placental carnivora, the ape and man, there is a parallel rise and homology of type in all these parts. In the elephant and porpoise, however, notwithstanding their enormous cerebellum, the olive is of no higher a grade of development than in the hippopotamus. (In the elephant the olivary lamina is more bulky.) If any evidence were to be derived from comparative anatomy, it would show that there are two types of olivary development, one marked by a progressive complication of the denticulate part of the olive found in animals with freely movable digits, and one in which the accessory nuclei nearly equal, or even preponderate over the main U-shaped, respectively dentate nucleus, which is the case in the pachydermata and the cetacea, who are in no case endowed with free digital motion and co-ordination. But for the apparent connection between digital motivity and olivary type, I would hazard the suggestion that the development of the olives suggests a greater affinity, zoölogically speaking, between the pachydermata and the cetacea than I have hitherto been inclined to admit (Recent Studies in Localization, Chicago Journal of Nervous and Mental Diseases, 1877).

[1] Starr, loc cit., p. 63.

[2] Comparative Anatomy is competent, I think, to settle some of the questions indicated. In the porpoise the relations are most aberrant. In the usual situation there are no pyramids, nor a decussation either of pyramid or interolivary fibres. There is but *one* of the columns of the posterior columns, in anything like the ordinary development, and an atrophic state of the posterior columns generally in the uppermost cervical levels. The "Vorderstrang-grundbündel" of Flechsig are enormous, and consequently—the only exception to the rule in mammals—the anterior (ventral) fissure of the cord is deeper than the posterior in this region. Connected with this, probably, is the fact that the posterior longitudinal fasciculus, and the inner division of the reticular field are unusually large, constituting a united area which is parallel to the raphe. The nucho-dorsal innervations probably pass through this tract. There is a raphe, but unlike that of man, it is thinner ventrad than toward the nerve nuclei, where it is double the width of other points, and sends out the only powerful lateral processes it boasts of in the corresponding parts of the oblongata. The two olivary nuclei approach each other as in the elephant, and do not resemble in type the olivary nuclei of the carnivora, but the pachydermata (hippopotamus, horse, and elephant). The arciform fibres of the olivary decussational commissure do not take a course so near the lateral field of the oblongata as in man, but condensing in powerful strands break into what seems to represent the restiform column from the middle of the reticular field. In some levels there is no fissure nor raphe between the olives in their ventral portions. The main accession to the representative of the restiform column appears to be the direct transition of fibres from the posterior column through a field analogous to *f*, 3 Fig. 3) the arched fibre field which interpolates itself between the nucleus of Rokindo and that of Burdach, and which as its partial freedom from degeneration in my case shows, embodies fibres independent of the interolivary stratum. There appears still more cephalad to be a bodily transposition of the posterior into the restiform column.

At the junction of the oblongata to the pons there is a powerful fibre system, identified by the naked eye, which may indicate a decussation of ventral (pyramid or intermediate) fibres (?), but in connection with this there is also a development of a lateral ventral mass, attached to the auditory nerve, which is thus far not known to be paralleled in mammalian anatomy.

The pons, notwithstanding its great apparent surface development, is thin, that is, of slight dorso-ventral extent, and consists, as in the elephant, of transverse fibres and ganglia exclusively; there are, as in the elephant, no longitudinal, *i.e.*, pyramid fibres. Between the tegmentum and the pons, there is a system of nerve-bundles imbedded in ganglionic matter, which resemble in disposition the lemnisco-pedal bundle.

nuclei known to be related to visceral functions. It would, therefore, as far as the case of the porpoise stands, be a confirmation of the view that the columns of Clarke and the cerebellum which derives fibres from them through the direct myelo-cerebellar tract, have a relation to visceral functions; the mother-bed of the direct myelo-cerebellar tract corresponding in extent to the visceral segments, and its cells corresponding in shape to those known to have relations to the viscera. One end of the Purkinjean cell of the cerebellum, too, is as Meynert has ingeniously indicated, of a similar structure. If any inference is to be drawn from cell structure as to function, then the Purkinjean cell is a mediator between a visceral centripetal tract and a cerebral one, connected with the information of the motor centres as to the space sense. The case of the porpoise speaks as loudly for the "equilibrium" as for the "visceral" theory, inasmuch as the wonderfully co-ordinated movements of the porpoise are chiefly carried out by the trunk muscles.[1]

It it evident that within a large area of the medulla oblongata, one covering its entire field, with the exception of the pyramid tract, and the apparatus of the nerve nuclei, we must look for the centripetal tracts which inform the *Psyche* of the contacts with the outer world, the visceral sensations, and the muscular sense. Many of the movements dictated by the perfective economical needs of the body are not directly mediated through the apparatus of consciousness, indeed many of them are absolutely removed from the control of the *Psyche*.[2] That the translation of the peripheral impression to the centrifugal impulse, in their case, takes place without the intervention of the cerebrum, is evident. The ganglionic apparatus of the cord, and in higher degree of the oblongata, suffice for these objects. It is a fact of significance, that of the reflex and automatic actions which are made to serve these objects, those determined in the mesencephalon, pons, and oblongata far exceed in complexity and elaboration those of the cord, and in direct proportion to this complexity and elaboration do they display an approach to intelligence. It is a dogma of physiology that all the intricate automatisms of the brain-axis, be they subservient to respiration, thermic regulation, or nutrition, depend for their origin and development on impressions indicating the nature of the organic need.[3]

We must here assume as an element in our calculations, that the area of the oblongata within which we are seeking for the centripetal tracts, includes some which we may never be able to determine, because their disturbance is not made manifest to consciousness, not discoverable by instruments of precision, and cloaked by vicarious action of the symmetrical ganglionic apparatus. While unilateral *irritative lesions* may enlighten us in this field, through positive symptoms produced, *subtraction lesions*[4] must be bilateral in most cases to do so.

There are other functions, carried on by centripetal tracts, which are subservient to needs which constitute a connecting link between the vegetative and deliberate purposes: they regulate the bodily equilibrium. Notwithstanding the many objections repeatedly urged to the older view regarding the cerebellum, the proposition formulated by me some years ago, that a skilful and rapid co-ordination, associated with a good sense of rhythm, space, and time in connection therewith, was not possible without an intact and well-developed cerebellum, does not seem to be invalidated by any authentic case, while it is confirmed by a large number of observations.

The higher form of sensation, that of conscious perception, travels through the area left over after the subtraction of the cerebellar tracts. Inasmuch as there is an intimate dovetailing of lemniscus, reticular, and cerebellar tracts in this area, in the lower half, and indeed nearly in the entire level of the oblongata, accurate and positive conclusions as to the differentiation of pain thermic, and tactile tracts in the reticular formation and lemniscus, can be derived—as far as the study of single cases is concerned—from such only where the focus of disease is situated above the level of the fully formed posterior cerebellar peduncle. Of these forms of sensation, the highest, or rather the one made subservient to the most intellectual purposes, is the stratum interolivare, which conveys the so-called muscular sense brainward, for the purpose of facilitating skilful employment of the psycho-motor centres. All studies made so far fail to give any satisfactory account of the *raison d'être* for the paradoxical phenomenon observed by Brown-Séquard—that the tract for one sense, which is in part but a refinement of associated peripheral impressions, should not decussate in the cord, but decussate in the oblongata, while the others should decussate in the cord, and—redecussation being fairly excluded, inasmuch as that assumption would be still more out of harmony with the facts than any other—not decussate in the oblongata. There is no physiological theory, nor mechanical factor of development, nor, as yet, are there adequate anatomical paths, to explain why the ordinary sensory channels should, so soon after their entry, seek the opposite side of the cord to travel brainward in. It is for this reason, I believe, that so many teachers of cerebral anatomy have contented themselves with tracing the great tracts from and to the level of the first cervical nerve-root, until Wernicke formally opened a question—and answered it as satisfactorily as any one up to the present—which had probably confused or puzzled all of his co-laborers.

[1] This animal, provided with clumsy flippers and a rudimentary dorsal fin, is capable of executing evolutions exceeding anything in the vertebrate domain, not excepting the blinded bats of Spallanzani, for they involve at once gross force and skill. The porpoise executes his remarkable evolutions around his own axis, while rushing along with the speed of a steamer, and it is a notorious fact that cohabitation—an act requiring the ordinary mammalian mechanism—is carried on while the herd is tumbling along with undiminished speed. All is done by the axial muscles.

[2] Fortunately too!

[3] I do not enter here into a discussion of Van der Kolk's beautiful theory of respiration as the outcome of a direct rhythmical asphyxia of the oblongata.

[4] Lesions involving elimination of nervous mechanisms.

ON THE NERVOUS ORIGIN OF SOME DISORDERS OF THE ALIMENTARY CANAL.[1]

By LEONARD WEBER, M.D.,

NEW YORK.

The following observations on the often misunderstood disturbances of the gastro-intestinal tract of nervous origin will contain nothing new to those familiar with the diseases of the nervous system, but will be of interest to the practitioner, I believe. As to the theory of these affections, it must be remembered that Leube, in an article entitled "Dyspepsia Nervosa" (*Deutsche Zeitsch. für Klin. Med.*), thought the latter to be peripheral neurosis of the stomach, affecting the central nervous system by reflex only. It cannot be denied that such cases may occur, but they are certainly very rare.

I believe, with Beard, F. Richter, Möbius, Leyden, Burkart, and others, that nervous dyspepsia, etc., is not of local origin, but a symptom of general neurosis, particularly of cerebro-spinal neurasthenia. Organic diseases of the nerve-centres may, also, reflex severely upon the functions of the stomach, when the pneumogastric centre or the cervical portion of the cord or the abdominal ganglia of the sympathetic have become the seat of lesions.

Between twenty and thirty per cent. of patients with organic nervous disease have gastric or intestinal disturbances. Periodic vomiting and retching—crises gastriques of Charcot—often constitute prominent and early symptoms of typical tabes, but they have been observed also in subacute myelitis, disseminated sclerosis, and progressive paralysis. But similar paroxysms of severe retching and vomiting, associated with violent gastric pain, great tenderness in the epigastrium, and the impossibility to retain food, lasting for two weeks and more, simulating gastritis or ulcer, and presenting considerable

[1] Read at the meeting of the New York Neurological Society, October 7, 1884.

difficulties of diagnosis, have been observed occasionally independent of anatomical changes in the stomach or central nervous system. Leyden, in an article on "Periodical Vomiting and Gastralgia," published in the *Deutsche Zeitsch. für Klin. Med.*, iv., 4, p. 605, 1882, reports four cases, one of them, in a man forty years of age, coming on after protracted mental overwork, and ending fatally. I have had two well-marked cases of the kind under my charge, both concerning young women, in the etiology of which menstrual disturbances played an important part. Ice applications, morphine injections, and the blandest possible diet failed to bring relief. But after raising a blister over the stomach, putting neither food nor drink into it, and supporting the patients by rectal alimentation for some days, improvement and final recovery took place. Constipation and diarrhœa, hyperesthesia and neuralgia of the stomach, are quite frequent in neurotic females, particularly when they have uterine trouble. In neurasthenic men, diarrhœa, quite independent of catarrh or other local causes, is not very rare. An interesting and obstinate case of periodical attacks of nervous diarrhœa has been under my observation for some years. F. S——, about forty years of age, a merchant, the father of healthy children, of strong constitution, excessively nervous, showed the first symptoms of the disorder eight years ago, while engaged in active and difficult business. He has been carefully examined by myself and others, and had the counsel of eminent specialists. But no one has arrived at an anatomical diagnosis in his case; a nervous origin of it is almost certain, the more so as his father, who is still alive, has been suffering from the same trouble for many years.

Various modes of treatment have given but temporary relief, the attacks growing rather more severe and persistent as time goes on, and are frequently complicated by vomiting and gastralgia. Having found that he can make himself more comfortable by morphia than by any other remedy, the patient has of late become somewhat of a morphine-eater. The rather frequent and more readily tractable forms of nervous dyspepsia, etc., we may designate, with R. Burkart, as gastric neurasthenia. The difficulties and discomforts experienced while digestion goes on, constitute the principal complaint in these cases. All other intercurrent symptoms depend upon the exacerbation and remission of the former.

Such other cerebro-spinal symptoms are headache, vertigo, cardiac palpitation, backache, depression of spirits, disturbed sleep, etc. This array of symptoms gives us a clinical picture quite different from the symptomatology of catarrh, carcinoma, or gastric ulcer.

There is often a sensation of fulness and pressure in the epigastric region, frequent eructation, occasional vomiting, tympanites, and flatulency. Sometimes there is anorexia, and again ravenous appetite; bowels generally irregular, alternately loose and constipated.

R. Burkart, in an excellent monograph on "Neurasthenia Gastrica," Bonn, 1882, describes a new symptom, *i.e.*, hyperæsthesia of the abdominal ganglia of the sympathetic. He has found it in almost all his cases of neurasthenia gastrica, and mentions three localities for examining for the tender ganglia: 1. Plexus hypogastricus. The patient being in the horizontal position, pressure is made with two fingers of both hands in the median line, below the umbilicus and a little above a line that would connect the spin. oss. ilei, perpendicularly downward against the vertebral column. In neurasthenia gastrica we shall find in this way an exquisitely tender spot, from which painful sensations will radiate downward and particularly upward. A feeling of oppression will sometimes come over the patient while the pressure lasts. A second place corresponds to the plexus cœliacus; but pressure over that discloses less hyperæsthesia, and reflex symptoms are absent. Finally, the plexus aorticus may also be the seat of hyperæsthesia. Per contra, he has not found any hyperæsthesia of the above ganglia in neurasthenia without gastric symptoms, nor in cases of anatomical disease of the gastric intestinal tract.

The disproportion between the objective signs and the numerous complaints is quite characteristic, and the discomfort is sometimes greater when the stomach is empty than when it is full. While diet has no great influence, emotion, worry, and excitement, and intellectual or physical overwork have so much the more in precipitating an attack. The condition of the patient is variable; there are periods of great distress, followed by partial or complete well-being.

The morbid influences most potent in producing gastric neurasthenia are: acute diseases, intellectual overwork, great emotion and excitement, hereditary neuroses, and the various sins of civilized life. The prognosis of this class of cases is generally favorable. Therapeutically they need generous quantities of nutritious food, good air, and particularly mountain air, and ought to follow a suitable regime in sexual indulgence, and in mental and physical occupation. Bitter waters and saline purgatives in general are contra-indicated, according to my experience. The waters of Saratoga, Carlsbad, and similar places do harm, and the more so, the stricter the diet that has been observed while using them. I have seen patients of that class come back from Carlsbad worse than they were before they went. Hydrotherapeutics in the shape of tepid half-baths with cold affusions, or the wet sheet with friction of the whole surface of the body, are often of service, and so is massage, generally and gently applied. Galvanism applied every other morning to head, spine, or sympathetic, according to the indications of the case, is frequently of good influence. Of drugs I am in the habit of prescribing small doses of an acid solution of the comp. hypophosphites between meals, more than anything else. They are generally well borne by the stomach, and I consider them a good tonic for a neurasthenic person.

25 West Forty-sixth Street, New York.

MINERAL ASTRINGENTS AND CAUSTICS IN OPHTHALMIC PRACTICE.[1]

By EDWARD S. PECK, M.D.,

visiting surgeon to charity hospital, new york.

The motive of this paper was suggested to me by remarks made by a member of this Society, some time ago, relative to the use of various mineral astringents and caustics in the treatment of eye diseases. It occurred to me that it would not be amiss to offer the present views of their use, with special reference to nitrate of silver, as a monthly contribution, and to endeavor to differentiate their position in ophthalmic pharmacology.

Conjunctivitis.

The different forms of conjunctivitis may be classified as *catarrhal, vernal, follicular, granular, blennorrhöic, croupous, diphtheritic*, and *phlyctenular*.

a. Catarrhal conjunctivitis, or conjunctivitis simplex.—The general characters of this affection are increased hyperæmia of the conjunctiva and increased secretion. The hyperæmia is often very pronounced; the secretion is purely catarrhal, consists of mucus, epithelium, and fat-cells, is a trifle opaque, viscid, and when it becomes dry the lid-edges are disposed to stick together.

Every abnormal secretion of the conjunctiva, produced by inflammatory processes, is to be regarded as contagious.

A simple catarrhal conjunctivitis is not always amenable to treatment; it may become chronic; or it may produce lymphatic infiltration in the vicinity of the culde-sac; or it may involve enough of the under-lid to create an eversion of the lachrymal puncta; or there may be an ulcerative blepharitis, or a secondary trau-

[1] Read before the Northwestern Medical and Surgical Society, April 18, 1884.

matic keratitis. Such are some of the members of the vicious circle possible to every acute catarrh of the conjunctiva.

As regards the use of nitrate of silver in the different forms of conjunctivitis, Graefe [1] elaborated the principles to be carried out in a masterly paper on diphtheria of the conjunctiva. His work in this direction rehabilitated the caustic from the disrepute into which it had fallen. The empirical use of the silver-nitrate is unnecessary, inasmuch as its indications in different forms of conjunctivitis are tolerably precise. Some of these indications I desire to note here:

1. The use of silver-nitrate always presupposes an increased flow of blood to the conjunctiva, with a certain amount of succulence of tissue and serous exosmosis; and the more pronounced the hyperæmia of the membrane with its secondary developments, the more, *cæteris paribus*, is the nitrate indicated.

2. Silver-nitrate is not indicated in any form of conjunctivitis attended by a fibrinous, easily coagulable secretion, so long as this kind of secretion persists. It frequently happens that blennorrhöic affections of the conjunctiva have an initial stadium, in which the secretion is easily coagulated when the superficies of the membrane is smooth and glistening on account of a highly injected mucous membrane. To apply the silver-nitrate on such a membrane would be to impair its integrity, to increase the fibrinous exudation, and possibly to induce a severe disease of the cornea.

3. Silver-nitrate is contra-indicated in deeper inflammatory processes of the eye, as, for instance, in certain diseases of the cornea.

4. The strength of the nitrate must be in proportion to the intensity of the inflammatory changes of the conjunctiva; that is to say, a severer grade of conjunctival inflammation demands a stronger solution of the nitrate. These solutions vary from a half to one and a half per cent.

5. The strength of the nitrate must be reduced in proportion to the disappearance of the inflammation.

6. An eschar forms after the application of the nitrate, under which regeneration of the disturbed tissues takes place. The nitrate should not be reapplied until after the regeneration of the tissues.

7. The influence of the nitrate upon other tissues should be prevented; for this purpose either simple water should be used to wash away the resulting silver-albuminate, or with stronger solutions of silver a solution of common salt should be used.

The details of application need not be given here. It is sufficient to note that silver-nitrate is the astringent to be used over all others in *catarrhal conjunctivitis*.

b. Vernal conjunctivitis.—This is an endemic form of catarrh, showing itself in the spring. It is confined to the limbus conjunctivæ and to the adjacent part of the bulbar conjunctiva. As a rule, there is no excess of secretion, and the affection is to be regarded as a chronic conjunctivitis. The membrane is of a dirty red or a lustreless pink color; it lacks the freshness and vitality peculiar to other forms of conjunctival injection. This is probably due to a serous infiltration which occurs in irregular spots under the conjunctiva. The disease is marked by unusual photophobia.

To the inexperienced practitioner there is a great temptation to use the silver-nitrate, but it will only increase the symptoms, and thereby possibly endanger the cornea. In the event of a discharge, a weak solution of silver-nitrate, as one per cent., could be used with benefit. The photophobia must be regarded, however, as contra-indicating the use of silver; such metals as zinc or lead would be preferable.

c. Follicular conjunctivitis, properly named from the development of superficial, globular, pale-red prominences, which accompany catarrhal inflammatory changes in the conjunctiva, and which latter, on subsiding, carry away with them quite every vestige of follicular growth. Follicular differs from simple catarrh in this development of follicles. Like simple catarrh it has a secretion mild in character, while, unlike it, the follicles may be regarded as lymph-follicles; that is to say, their structure is that of the closed lymph-sacs, while the smaller, smooth, whitish bodies may be regarded as collections of lymphoid elements. To carry out the analogy between the follicular and catarrhal forms, it is to be said that the development of follicles protracts the course of a conjunctivitis, renders it more obstinate to absorption processes, and more disposed to a recurrence; on the contrary, there are not the inflammatory changes in the deeper tissues of the lid in follicular conjunctivitis which obtain in granular conjunctivitis.

Secretion of an acute follicular is more contagious than of a simple catarrh of the conjunctiva. This is the form usually found in the different members of a family, in schools, barracks, etc., though other causes may conspire to extend the eye disease, chief of which is the bad ventilation of such inhabited rooms. Among the causes of follicular conjunctivitis is to be reckoned the traumatism due to a long-continued use of irritating remedies, such as different mercurial ointments applied within the lids, so much in vogue in South Germany, atropine, etc. Although atropine may have been used for weeks without any conjunctival reaction, suddenly, without any warning, a follicular inflammation of the conjunctiva may be developed, with marked injection and œdema of the lower lid, which latter may extend to the lid border, and eventuate in a blepharitis, or may go over on the integument of the lid and cheek, amounting to a dermatitis miliaris. One peculiarity of atropine-conjunctivitis is its long duration and resistance to treatment; these characteristics are entirely independent of the length of time atropine has been already used, whether long or short.

As to the management of cases of follicular conjunctivitis, it is to be observed, that while silver-nitrate is the astringent of all others to be relied on, it is, however, not to be used early in the case. Antiphlogistic measures are first to be resorted to; such as ice-cloths, of one thickness of a square of old muslin, transferred from raw ice to the eye; scarifications, if the lid is hyperæmic and swollen, made parallel to the fold of the lid; while later, and not until the incisions have healed, the silver-nitrate, not stronger than one per cent. It goes without saying, that all such cases must be eliminated of their hygienically bad relations, placed in new rooms, or, at least, in freshly fumigated old rooms, as when the treatment is conducted in the wards of a hospital, the dormitories of lodging houses, boarding-schools, etc.

d. Granular conjunctivitis.—The general characteristics of this form of conjunctivitis are so well known that it will be hardly necessary to enter into a detailed explanation of its pathological exhibits; it has various forms, which are arranged under different names, and require different plans of treatment according to the different stadia of the pathological process. The terms *granulations*, *trachoma*, etc., imply technical states and qualities of the granular and granulating process. An analogy is often drawn between this and the follicular form of conjunctivitis; but the similarity is external and superficial, and is based upon the fact of the formation of prominences on one and the same conjunctival tissue. The follicles in the one variety are purely superficial, and disappear without leaving a trace of their existence; while the granulations are formed from the cellular tissue layer, push the epithelium before them, and leave a cicatrix where they previously rested. Viewed in this way, granulations belong to the neoplastic growths, as does a true granuloma. Further, granular conjunctivitis—that is, granulations—may exist not only on the palpebral, but also on the bulbar conjunctiva, and may extend even to the limbus of the cornea; while it is well known that no papillæ exist in these last two locations.

[1] Von Graefe: Arch. f. Ophthal., vol. i., part i., pp. 168–250.

It is not to our purpose to dwell on the different subdivisions of granular conjunctivitis, as the acute, the simple or chronic, and the cicatricial, nor to go further than to mention some of the possible vicious complications, as *e.g.*, contraction and bending of the tarsus; dryness of the conjunctiva, or *xerosis;* diseases of the tear-passages, as stenosis, stricture, and imflammation of the lachrymal sac, eversion of the inferior punctum, and ectropion of the inferior lid; changes in the lashes, as malposition and improper growth; and lastly, diseases of the cornea.

The secretion of granular conjunctivitis is contagious; the contagion depending on the secretion itself, and not on the granulations. The secretion of the acute is contagious in a higher degree than that of the chronic form. Arlt has stated that there was a legitimate connection between scrofula, or tuberculosis, and trachoma; but every practitioner knows that granular conjunctivitis frequently develops in robust and perfectly healthy individuals; also, that impoverished persons contract it as well as those well fed. Inhabitants of high altitudes are less liable to its attack and severity than dwellers in low and damp districts. Finally, granular conjunctivitis attacks individuals of ten to thirty years of age most frequently; during the first and after the forty-fifth year an initial attack is seldom observed. It is a disease of the poor people, and not of those in good circumstances and in the practice of decent hygiene.

As to the therapeutics of granular conjunctivitis, the acute form is best treated, from the indicative inflammatory symptoms, by cold applications, scarifications, and later by astringents; while the simple or chronic form is best treated by astringents. Should corneal affections develop, as the result of persistent, pericorneal injection, in the form of acute infiltration of the periphery of the cornea, or as abscesses, the treatment must be limited to atropine, and every kind of caustic be abandoned. For the final stage of an acute granular conjunctivitis, after inflammatory symptoms have been removed by cold, and the serous infiltration by scarifications, the best caustic to be employed is nitrate of silver, in solution, one to one and a half per cent.; but in the chronic form, the astringent to be relied upon beyond all others is the sulphate of copper, the copper-stick or blue-stone, as it is popularly known. It is enough merely to mention that removal to pure, dry air, cleanliness, freedom from dust and smoke, and, if in a hospital, the limitation of patients to the more open and better ventilated parts of the ward, must be insisted upon; if, too, in a hospital, such patients ought not to be allowed to converse at the bedside of others who have had intra-ocular operations, such as those convalescing from extraction of cataract, iridectomy, or paracentesis; nor, on the other hand, should they be allowed too close proximity to open wounds, erysipelas, pyæmia, and puerperal fever. The same precautions, though in a more emphatic sense, should be insisted upon with hospital patients under treatment for the various forms of blennorrhöic conjunctivitis, such as the purulent ophthalmias of the adult and newly-born, diphtheritic conjunctivitis, etc. Though at the risk of being criticised for a digression, I take great pride in noting that for the last four years of operative work in the ophthalmic wards of Charity Hospital, not a single operation has been endangered by the presence of trachomatous patients; and, as is well known, granular conjunctivitis abounds in the ophthalmic division of the hospital, sometimes *ad nauseam*.

Neither the purpose nor the limit of this paper will allow anything more than a reference to the cicatricial stage of granular conjunctivitis; it is properly a stage of contraction and distortion of the tarsal ligament and lid, or a stage of deformity, and for which treatment is chiefly surgical. The operations for blepharophimosis, as canthoplasty, cantholysis, etc., the different procedures for the relief of ectropion of the lid, eversion of the punctum, reposition of the cilia, trichiasis, and distichiasis, as also for stenosis of the tear-sac, stricture, etc., can here be merely alluded to. They are operations naturally relegated to the specialist, some of which belong to the nice calculations of cosmetic surgery.

e. Blennorrhöic conjunctivitis.—It is characterized by the generation of a well-marked purulent secretion from a highly vascularized membrane, infiltrated with serum, and covered with granulations. The secretion is its chief differentiating factor. There are two varieties of blennorrhœa—acute and chronic. An acute blennorrhœa is usually binocular (double-sided). It first shows itself in reddened and partially swollen lids. The swelling can involve a part or the whole of the lid—can extend to the bridge of the nose, and may be of such amount that the upper lid can be raised with difficulty, and the palpebral slit be seen scarcely at all. A smoky, thinly fluid, copious secretion begins early to course from the palpebral opening, capable of being drawn out in elastic threads. So strongly injected is the conjunctiva, both palpebral and bulbar, that frequent *apoplexies* result; the injection and infiltration may extend up to the cornea, even overhang it, and limit its diameter; this condition of strangulation of conjunctival vessels is called *chemosis*, and on eversion of the lids a thick welt of bluish-red tumor is seen between them. So soon as this glistening, distended mucous membrane is exposed to the air, the thin exudation is quickly followed by a new discharge. A burning heat with severe pain in the eyes and brows accompany the inability to open the eyelids, while the crypts between and underneath the false folds of conjunctiva are choked with a rich exudation of a highly contagious, purulent discharge. Subsidence of infiltration takes place in a few days; the secretion diminishes in quantity, but becomes more consistent, and wells up like a whitish-yellow cream. After continuing from two to three weeks the inflammatory symptoms begin to disappear, the lids can be more easily opened, the secretion becomes more mucous, the injection, infiltration, and granulations subside *graduatim*, and in from six to eight weeks the main elements of this special disease have disappeared. This long-continued pressure on the (anterior) ciliary arteries tends to impair the integrity of the cornea, and to produce secondary affections of that tissue. There may follow this stasis either superficial ulcerations at the periphery, or deep pus-dépôts in any part of the cornea, with abscess and perforation, iris-prolapse, traumatic iritis, etc.

Chronic blennorrhœa differs in the degree of primary inflammatory symptoms, the secretion is more mucopurulent in character, and easily dries on the lashes. More than in the acute form, granulations develop, and ultimately may lead to shrinkage of tarsus and ectropion. The chief anatomical changes in blennorrhœa consist of the thickening of the stroma of the conjunctiva, the distention of the vessels, and the thickening of their adventitia. A simple conjunctival catarrh may eventuate in a blennorrhœa; a conjunctivitis, not originally catarrhal, may eventuate in a blennorrhœa; as, for instance, an acute granular conjunctivitis, or a croupous or diphtheritic form. In fact, a true diphtheria of the conjunctiva, while itself rare, usually ultimates in a blennorrhœa.

The most common cause of a blennorrhöic conjunctivitis is the conveyance of a similar secretion from any mucous membrane, either of the patient or of another person, and that mucous membrane may be conjunctival, vaginal, or urethral. This contagion may be conveyed by actual contact, or by transmission through the air. Further, the daughter-conjunctivitis will not necessarily be the same as the mother-conjunctivitis.

The management of blennorrhœa must be conducted on two lines: 1, protection; 2, therapeusis. It is of the highest importance that, in case the affection is of one eye, the other should have a protective bandage; that in every case the greatest precaution should be taken against the possibility of a conveyance of discharge to the attendants. Towels, sponges, and compresses should

never be twice used without thorough cleansing and disinfection, and applicating cloths should be burned. Treatment proper should be guided by the phase of the process, by the character of the mucous membrane and the secretion, and by the corneal implication, if any be present. The following general rules should be followed: 1. If the mucous membrane be smooth and shiny, and covered with a thin and transparent or slightly cloudy exudation, or if there be a thin and fluid secretion of a gray or light yellow color, cold applications must be used, while caustics must be avoided. 2. If the tissues are swollen or chemotic, scarifications must be made, followed by cold applications. 3. If granulations—that is, papillary bodies in folds—have developed, if the lid-swelling has begun to subside, if there be not a thin, glairy exudation, but, on the contrary, a thick yellow-homogeneous secretion, then caustics are indicated. 4. If the cornea be involved in the last picture of granulations and discharge, then caustics are indicated, because so long as they successfully fulfil their indication the progress of corneal disease is abated.

There is, perhaps, no conjunctival disease in which the caustic treatment meets with such eminent success as attends its adoption in proper time and strength in blennorrhöic conjunctivitis. It is a fundamental principle that the strength of the caustic must be proportioned to the intensity and development of the inflammatory processes; at the same time the caustic must be used at the beginning weaker than the grade of the inflammation would indicate, and may be strengthened little by little as the mucous membrane shows a tolerance. In this regard is shown the judgment of the practitioner, to preserve the balance of power, so to speak, on the side of the disease and not on that of the caustic, as it is always easier to increase the strength of the latter, if required, than to combat the injudicious effect of a too powerful caustic. Among the possible bad effects of too powerful astringent treatment is the destruction of the corneal epithelium, perhaps already undermined by the blennorrhöic processes. Solutions should average of the strength of one to two per cent. Corneal disturbances, as simple or necrotic keratitis, abscess, or keratitis profunda, are to be treated with atropine, one-half to one per cent; as corneal involvements are usually sequels of the acute inflammatory stage, caustics will have been resorted to, and their use may be continued, but with care.

In this category belongs the blennorrhœa of the newly-born, of which but little need be said, as it is easily recognized by the character of the discharges and its appearance in two or three days after birth. It is a strange statement, and to some may be new, that not every case of blennorrhœa of the infant is developed from a blennorrhœa of the vagina of the mother; but without doubt the majority of the cases do so develop. I have treated many cases of blennorrhœa, beginning within forty-eight hours of birth from no traceable cause, in which at no time was there a discharge greater than what might occur in a mild catarrhal conjunctivitis, and which came to good recovery in a few days under mild caustic treatment and cleanliness. In the blennorrhœa of the newly-born, as in that of adults, the same question arises as regards the continuance of the caustic treatment during corneal complication, such as keratitis profunda, abscess, etc.; it may be emphasized on the part of infantile blennorrhœa, that such treatment is not only not contra-indicated, but, on the other hand, may be pursued with advantage. The surgical measures necessary in abscess of the cornea, as puncture, and removal of a prolapsed iris, will only be mentioned here.

The forms of conjunctivitis known under the generic heads of croupous and diphtheritic need not claim our attention; they are rare, even in a large special practice, are not necessarily coincident with croup or diphtheria of the air-passages, and do not indicate caustics as an *essential* element in treatment. Caustics, however, are to be used after the pseudo-membrane has been removed, and the process becomes a secondary blennorrhœa.

The last variety of conjunctivitis to claim our notice at this time is the

f. Phlyctenular.—It is introduced here by way of negative argument as to caustics; that is to say, they are not to be used in any stage. A brief summary of its characteristics should be given. One of the most common of all ophthalmias, and chiefly among children before their fifteenth year, it is begotten in scrofula, bad hygiene, or poor living; it is limited to a small portion of the bulbar conjunctiva between the corneal periphery and the cul-de-sac; it is known by its pimple or bladder-like prominences, which may be single or multiple; the phlyctens or swellings may become abscess-like, and may form—to use an anomalous expression—an elevated ulcer. The disease has a peculiar tendency to extend itself in the form of phlyctens upon the cornea, even to the centre of its face. Patients with phlyctenular conjunctivitis have such scrofulous exhibits as the following: eczematous and impetiginous eruptions in the vicinity of the lids, at the nasal angles, on the upper lip, behind the ears, and on the hairy portions of the body; glandular swellings, other mucous catarrhs, etc. Phlyctenular conjunctivitis is not contagious, as are the diseases already described. Frequently no abnormal secretion attends it; on the other hand, it is to be noted that the phlyctenular form is a frequent sequel of other diseases in other parts of the organ—such as blepharitis in scrofulous subjects, disturbances of the tear-passages, episcleritis, etc.

The treatment in brief follows these lines: 1. Iron and cod-liver oil; a proper diet and hygiene to combat any possible scrofula and the tendency to blood-impoverishment, of which this disease is an index. 2. Irritation by calomel, and by ointments of the red or yellow mercurial oxide placed within the lids. 3. The avoidance of all derivatives and depressants. 4. The continuance of topical remedies long after all inflammatory changes have passed away. For the photophobia, always present, and which in children is known by the peculiar manner in which they blink at you from under the bent arm, the sovereign remedy is ducking the face in cold water.

Finally, in connection with the treatment of mucous membranes by the silver-nitrate, it should be noted that the excessive use of this salt produces a discoloration called *argyrosis*, or a silvering of the papillæ of the corium. While this is a frequent result of the internal use of silver, as for epilepsy, chorea, etc., it is quite rare as due to topical application. Professor Neumann, of Vienna, once showed the author of this paper a section of the lower lid in a condition of argyrosis, which in a bright light gave the beautiful lustre of veins of silver where the papillæ of the corium were discolored by the silver-nitrate.

53 West Fiftieth Street.]"

Eczema and Trophic Centres.—Dr. F. A. Groat, of Fremont, O., writes: "In an article in The Medical Record of March 15th the question is asked, 'Is congestion of the trophic skin-centres the cause of eczema?' Since reading that article I have met with a case of vesicular eczema which seemed to be peculiar, in that it was developed only over the superficial muscles of both hands supplied by the ulnar nerve; making its appearance with the advent of warm weather, for six consecutive years, only upon these muscles, and never having been benefited by treatment, local or internal, alone or in combination. The man was unusually well developed physically, with no apparent indication of disease, unless obesity be pathological, and no local cause for the eruption to be found. If from congestion of the nerve-centre, would it manifest itself only in muscles supplied by terminal branches of the nerve?"

THE LAWS OF DISSECTION.

By HENRY A. RILEY, Esq.,

NEW YORK.

The laws of most of the United States, and of England as well, provide for the lawful dissection of human bodies in the interests of medical science. These laws are, most of them, of recent origin, although the first enactment in England was passed as early as 1540, in the time of Henry VIII. It was then declared that the Masters of the Mystery of Barbers and Surgeons might take each year four persons executed for felony, for anatomies, and to make incision of the same dead bodies, or otherwise to order the same after their dissections at their pleasure, for their further insight and better knowledge, instruction insight, learning and experience in the science or faculty of surgery.

In 1565 Queen Elizabeth allowed the College of Physicians similar privilege of dissecting annually four felons. In 1752 George II. permitted the bodies of all murderers executed in London and Westminster to be delivered to the surgeons for anatomical purposes. Notwithstanding these enactments, the supply of bodies for dissection was not sufficient for the demand, and numerous attempts were made by grave-robbers to meet the wants of medical students. In 1830, the act known as the Anatomy Act was passed, and it is in pursuance of its provisions that the medical profession in Great Britain now secure material for dissection and instruction. This act provides for the licensing of persons practising anatomy, and establishes inspectors of the various schools. The principal section of the act is as follows: "It shall be lawful for any executor, or other party having lawful possession of the body of any deceased person, and not being an undertaker or other party intrusted with the body for the purpose only of interment, to permit the body of such deceased person to undergo anatomical examination, unless to the knowledge of such executor or other party such person shall have expressed his desire, either in writing at any time during his life, or verbally in the presence of two or more witnesses during the illness whereof he died, that his body after death might not undergo such examination, or unless the surviving husband or wife or any known relative of the deceased person shall require the body to be interred without such examination." This act in its preamble declares that the legal supply of human bodies for such anatomical examination is insufficient fully to provide the means of such knowledge, and its effect, as stated by Justice Stephen in Queen *v.* Price, L. R., 12 Q. B. Div., 247, has been "that the bodies of persons dying in public institutions whose relations are unknown are so dissected." The duty of properly interring the remains after dissection is placed upon the persons giving the bodies to the physicians.

In New York the first law on the subject was passed in 1854, and it has been amended by legislative enactments passed in 1879, 1881, and 1883. The law as it now stands is clear, distinct, and satisfactory in its working. It is as follows: "It shall be lawful for the governors, keepers, wardens, managers, and persons having lawful control and management of all public hospitals, prisons, alms-houses, asylums, morgues, and other public receptacles for deceased persons, to deliver, under the conditions hereinafter mentioned and in proportion to the number of matriculated students, the bodies of deceased persons therein, to the professors and trustees in all the medical colleges of this State authorized by law to confer the degree of doctor of medicine. And it shall be lawful for the said professors and teachers to receive such bodies and use them for the purpose of medical study. Medical colleges which desire to avail themselves of the provisions of this act shall notify said governors, keepers, wardens, and managers of public hospitals, penitentiaries, alms-houses, asylums, morgues, and other public receptacles for the bodies of deceased persons in the counties where the colleges are situated, and in counties adjacent thereto, of such desire, and it shall be obligatory upon said governors, keepers, wardens, and managers to notify the proper officer of said medical colleges whenever there are dead bodies in their possession that come under the provision of this act, and to deliver said bodies to said colleges on their application. Provided, however, that such remains shall not have been desired for interment by any relative or friend of such deceased person within forty-eight hours after death; provided, also, that the remains of no persons who may be known to have relatives or friends shall be so delivered or received without the assent of such relatives or friends; and provided that the remains of no person detained for debt, or as a witness, or on suspicion of crime, or of any traveller, or of any person who shall have expressed a desire in his or her last illness that his or her body be interred, shall be delivered or received as aforesaid, but shall be buried in the usual manner; and provided, also, that in case the remains of any person so delivered or received shall be subsequently claimed by any relative or friend, they shall be given up to said relative or friend for interment; and it shall be the duty of said professors and teachers to dispose of said remains in accordance with the instructions of the Board of Health in said localities where such medical colleges are situated, after the remains have served the purpose of study aforesaid. And for any neglect or violation of the provisions of this act the party so neglecting shall forfeit and pay a penalty of not less than twenty-five nor more than fifty dollars, to be sued for and recovered by the health officer of said cities and places for the benefit of their department."

The great demand for bodies for dissection early outran the supply, as has been stated, and the art of the resurrectionists began to be developed. In the year 1788, forty-four years before the passage of the British Anatomy Act, the case of Rex *v.* Lynn, 2 T. R., 733, was tried. It was one of the first cases of the kind in the books, and puzzled the lawyers very much, notwithstanding the fact that the general subject of rights over dead bodies had been discussed by the text writers. In that case Lynn was indicted for a misdemeanor in disinterring a body for the purpose of dissection. It was urged on his behalf that the offence was only cognizable in the ecclesiastical courts, but the judges of the King's Bench declared that it was a fit matter for a criminal court, and said that common decency required the practice to be stopped, "being highly indecent and *contra bonos mores*, at the bare idea alone of which nature revolted." As the judges, however, thought that Lynn might have committed the act through ignorance, he was only punished by a fine of five marks. In some later cases the punishment was made severe, and at the present time there would certainly be no leniency shown to any one who removed a body unlawfully. In Regina *v.* Sharpe, 1 D. & B., 160, it was held to be a misdemeanor to disinter a body at all without proper authority, even when the motives for the act were laudable, it appearing that a son disinterred his mother in order to bury her in his father's grave in consecrated ground, but he was able to do this only by the use of a false pretence. The difficulty which the lawyers had in fixing the grade of the offence came from an inability to decide that a dead body could be property and the subject of theft.

Willcox, an old writer upon the laws of the medical profession, says that the whole question of the lawfulness or unlawfulness of taking bodies for dissection depends upon the answer to the questions: "Is it a violation of property? Is it a personal injury to any individual? Or is it an injury to the public? Every lawyer who has mentioned the subject has admitted that there is no violation of property in respect to the corpse itself, which is necessary to constitute the removal an offence; and Blackstone has distinctly stated that the only property violated is the grass and soil of the land wherein the body was interred, in respect to which the person may bring

his action of trespass, but the law has not provided any punishment as for an offence. It is equally clear that it is not an injury to any person; for the shrewd lawyers of Coke's time determined that the body was no person, but a lump of clay; and the only injury which can give a right of action to that, which amounts to a violation of any legal right of a relative or master, is such as may be said to recoil upon him by causing him expense, labor, or loss of valuable service." The theory of the early cases, such as that of Lynn, seems to be that the offence is one against the public, but this opinion is not now maintained against the abstract question of the use of bodies for dissection. It is no longer considered that any offence is committed against the person, against the public, or against property in dissecting the human body, provided this be done decently, for scientific or medical purposes, and in the mode prescribed by law. In the recent well-known case of Queen *v.* Price, decided by Justice Stephen, in Wales, no later than February, 1884, where it was held that cremation was a legal mode of disposing of the bodies of the dead, this language is used: "The law to be collected from these authorities seems to me to be this: The practice of anatomy is lawful and useful, though it may involve an unusual means of disposing of dead bodies, and though it certainly shocks the feelings of many persons, but to open a grave and disinter a dead body without authority is a misdemeanor, even if it is done for a laudable purpose." It was claimed in this case that the common law gave the *right* of Christian burial to every person, and that consequently cremation was illegal, especially if not directed by the deceased; but Justice Stephen held that the expressions implying a *right* of burial were used at a time when cremation was not conceived of as possible in England, and consequently no special importance is to be given to the words touching the lawfulness or otherwise of cremation. The same argument, if valid against cremation, would hold good in considering the question of dissection, for if Christian burial is a right and duty, it would preclude all use of bodies for anatomical purposes.

Following the English common law, the several States of this country have united in regarding the violation of tombs an indictable offence, and the intended purpose of the robbery, if it is dissection, does not mitigate the criminality of the act. In New York, for instance, removing dead bodies for the purpose of selling the same, or from mere wantonness, is punishable both by fine and imprisonment.

When the robbery of Mr. Stewart's grave occurred, some years since, it was thought by many persons that the law was powerless to punish the scoundrels if caught, but there would have been no trouble on this point. It is not at all likely that their object was dissection; it must have been to obtain the reward for the return of the body which they knew would be offered, and this would certainly come under the provision of the law forbidding the removal of dead bodies for the purpose of sale. In New Hampshire and Vermont the punishment for this crime may consist of fines, whipping, and imprisonment.

Actual presence at the time of the body-lifting is not essential to a conviction; but a person directing the proceeding, and near enough to give aid and assistance if required, can be punished as well as those actually opening the grave (Tate *v.* State, 6 Black, 111).

The considerations thus far produced treat only of the criminality of grave-robbery; some civil remedies for the same offence will be touched on at a future time.

A Foreign View of a New York Practice.—A Berlin medical journal publishes the following: "Dr. Beach(!), one of the first surgeons of New York (!), is living here at present. This gentleman has gained by his practice property to the amount of $5,000,000 (!). We are of the opinion," adds the editor, "that it is the specialists who are in the best way to accomplish these material results." It may be asked if the above paragraph is not part of a scheme to flood New York with Berlin specialists.

PSEUDO-BULBAR PARALYSIS.

Bilateral Apoplexy of the Lenticular Nuclei, Simulating Lesion in the Floor of the Fourth Ventricle.

By S. E. FULLER, M.D., and WM. BROWNING, M.D.,
BROOKLYN, N. Y.

It has not been thought possible as yet to include injury of the lenticular nuclei among the forms of brain disease which admit of approximate localization. A limited number of cases have, however, accumulated which seem to indicate that an insult to both these nuclei, and perhaps to only one, may produce a picture of its own.

Since, however, these bodies are, from statistics, a very frequent seat of apoplexy, and besides entirely latent foci have been found in them at the autopsy, it is probable that the special symptomatology observed in the other cases may have been caused, not by the lenticular injury itself, but by an extension of it or its effects to adjacent parts. Be that as it may, that injury of these bodies may produce a very well-marked and peculiar group of symptoms is shown by the following case. It occurred in the practice of Dr. Fuller, and was seen in consultation by Dr. McNaughton. The interest of the case was fully recognized and pains were taken to observe all symptoms. The clinical history is furnished by Dr. Fuller; the results of the autopsy are by Dr. Browning.

A lady, M. J——, aged sixty-one, had suffered three years previously a left hemiplegia without aphasia. Face, throat, and neck muscles reported to have been unaffected. Further particulars of the immediate attack unknown. She recovered from it fully. Toward the end of convalescence she came under my (Dr. Fuller's) care complaining of a severe burning sensation in the sole of the left foot. This was remedied with ergot and bromides. There were no premonitions to the present attack. It came on about 4 P.M., July 16, 1884, while in the bathroom. She is said to have called out to a lady in the next room, saying she was very dizzy and had pain in her head, the lady helped her to bed. There seemed to have been no loss of consciousness on the patient's part.

Upon my arrival she was speechless, and remained so. It was only possible for her to make an expiratory guttural sound. Having been paralyzed before, she immediately proceeded to show me that it was not the same by raising first the right arm and leg and then the left. The lips, tongue, and muscles of deglutition were paralyzed; the saliva flowed from whichever angle of the mouth was lowermost; the upper portion of the facial nerve was functionally intact and the pupils reacted normally. She could not open her jaws, or only to the slightest extent. The lower jaw could be readily depressed with the finger, but on attempting to swab out collecting mucus from the oral cavity and throat—as was often necessary—the jaws would close and press on whatever had been introduced into the mouth, despite the strongest desire of the patient to keep them open. The nurse had to be instructed, before cleansing the mouth, to wrap a blade in soft material and place it edgeways, so as to keep the jaws apart until the little procedure was finished. This symptom persisted during the conscious life of the patient. The tongue was quite motionless. The urine had been examined some time previously, and found free from albumen.

Immediately subsequent to this attack, there was an enormously increased flow of urine. In the first three hours she passed water three times. Though not measured, it was estimated by the attendants to have been a quart each time. In this urine there was about twenty vol. per cent. of albumen and once a trace of sugar with Fehling's test. Within twenty-four hours the quantity of urine returned to normal. Albumen persisted in it for a time at least. She snored very loudly after the attack, though not doing so previously. There was no trouble from the soft palate when awake, although it hung in a paralyzed condition.

So long as she remained conscious, *i.e.*, for the first

five days, she always gave notice of desire to defecate or urinate—no incontinence whatever. During the same period she would often motion for spectacles, paper, and pencil, indicating that the latter be first moistened in the mouth. She would then communicate by writing her questions, and showed the full possession of her mental faculties. This was farther shown by her remembering when medicine was due (given per rectum and hypodermically), by directing attention when a sample of urine had been forgotten, and in a variety of other ways, *e.g.*, curiosity as to the nature and cause of her own condition. She would, however, cry rather easily, the tears then running silently down over the cheeks. This could hardly be wondered at, or considered as loss of control over the feelings.

It is very doubtful if she succeeded in swallowing anything, though she tried hard to do so. She was successfully nourished with peptonized milk, etc., per rectum.

The sterno-cleido and other large neck-muscles did not appear to be affected. The sense of hearing remained good, and, in fact, no anæsthesia of any part of the body was discovered.

The pulse, respiration, and temperature showed no disturbance to within forty-eight hours of death. At this time, after some extra exertion on her part, she gradually sank into a stupor. Some twelve hours before the end she became very much flushed and hot to the touch over the whole body. This afterward gave place to a kind of collapse. Death on the morning of July 23d.

Post-mortem in the afternoon, with the assistance of Drs. Fuller and McNaughton. The autopsy being permitted only on condition that nothing whatever be carried away, it was impossible to make a minute examination of any of the parts, yet this could not have added very materially to the exactness of the present case. Only the brain was removed, including the cord to opposite the second cervical vertebra.

The cerebro-spinal fluid was slightly increased. The vertebral and carotid arteries with their branches on the base of the brain presented numerous patches of atheroma, but were, at least in all their larger divisions, still permeable. No farther abnormal appearances on any portion of the surface of the brain.

The lateral ventricles presented nothing unusual, unless some slight adhesions between the ependyma of the ventricular roof and floor. Laterally in the brain-substance, on the two sides very nearly symmetrical, were two fresh clots. These were in the lenticular nuclei, extending into all three divisions and tapering off posteriorly.

On the right side, in front of and external to the recent hemorrhage, were the remains of the former one. This was in the claustrum or between claustrum and external capsule. It extended from nearly opposite the front end of the ventricle to about opposite the front end of the recent hemorrhage, and was consequently just beneath the Island of Reil. There was simply an oblong space remaining, with slightly separated walls enclosing a little brownish, thick fluid matter. The said walls consisted of somewhat thickened and discolored tissue without any smooth interior surface. Such is, according to Charcot, the usual form and appearance of old extravasations at this point. This had clearly caused the former left hemiplegia. Motor fibres are not known to traverse this tract. The paralysis must, therefore, have been caused by pressure transmitted from the clot, a view which is corroborated by her recovery.

As to the recent extravasations, the same general description will apply to both. Each was in amount equal, perhaps, to a pigeon's egg. The nerve-tissue was not only much torn, but, from the size of the clot and its longitudinal form, also forced apart. The two were from their appearance of about the same date. It was not possible in either of them to distinguish any older or newer portion. They were very dark, in part semi-fluid, and, so far as color and character of the clot went, at least one or two days old, perhaps several.

The head of each clot was about opposite the front end of the thalamus, and diminished backward to nearly opposite the posterior end of the same. The main portion appeared to be wholly in the lenticular nucleus, while its posterior prolongation or branches may have encroached to a limited extent on other structures.

No further foci were found in any part of the brain. The medulla oblongata, pons, etc., presented no morbid appearance. Sections through these parts were made very close together, so that even a pin-head clot could not have escaped notice. An embolus or thrombus of a week's standing must have produced visible softening, so that they also can be excluded.

The recent apoplectic centres were so large and the tissue about them was so torn as to render them valueless for the localization of any single symptom. The interest of the case, however, lies in the peculiar combination of symptoms. These presented a complex believed to indicate lesion in a part that at the autopsy was found intact. To recall some of them: the paralysis was bilateral, quite symmetrical as regards both extent and severity, and occurred on the two sides simultaneously. There was no loss of consciousness. Immediately there was a greatly increased flow of urine, and which contained both albumen and sugar. There was also well-marked labio-glosso-pharyngeal paralysis. This forms a group of symptoms the cause of which is generally assigned to trouble at the base of the fourth ventricle.[1] Thrombosis or embolism of a terminal bulbar artery is credited with almost identical consequences, and apoplexy from one of the same vessels may not appear very different.

A limited number of cases presenting varying degrees of similarity to the present one have been brought together by Ross in his recent work on "Diseases of the Nervous System."[2] From these he concludes that destruction of the lenticular nuclei in whole or in part *may* produce nearly, if not quite, all the symptoms of lesion of the medulla oblongata. The cases described or abstracted by him, however, ran a slower course, and were less typical of acute bulbar trouble. Ross, in one place, calls this form pseudo-bulbar paralysis—a convenient term for the present. To explain this grouping of symptoms, he points out that the lenticular injury must affect fibres in their course, probably through the internal capsule, from the psychomotor centres in the brain-cortex to the nerve-centres in the medulla. He notes that consciousness may not be lost at the occurrence of this accident, but does not in any of his cases mention disturbance in the urinary secretion. Wernicke mentions the occurrence of bulbar symptoms in cerebral disease. He even cites a case of so-called pseudo-bulbar paralysis, where, however, the pathological condition varied materially from that under consideration. In the present case the two hemorrhages must have occurred at the same time. Although not into a part vitally so important as the medulla, yet from their size and after-effects they proved fatal.

Experimental destruction of one or both these nuclei has not established any facts available in localization. Ferrier, together with many neurologists, simply believes that hemiplegia may result from such injury when unilateral. But these cases, while not disproving, certainly do not confirm this.

As to the possibility of distinguishing between these two (the lenticular and the bulbar) forms, some points may be noticed. In the present case there were no convulsions; no paralysis below the throat; nothing unusual in pulse or respiration; evidently no trouble with the sense of hearing, but increased reflex excitability of the muscles of

[1] In Brain for July, 1884, J. D. Mann describes what he calls a case of pure apoplectic bulbar paralysis. The symptoms very closely resembled those in our own case. He writes: "There is not much difficulty in localizing a lesion such as this. The symptoms at once point to the posterior part of the rhomboid sinus." An autopsy would show whether such complacent confidence in his power of localization were warranted.

[2] Vol. ii., pp. 626–8 of first edition, continued in the second edition. Further two cases of depots in lenticular nuclei—one unilateral—are given by Ross, in Brain for July, 1882.

the jaw. In bulbar lesions the corresponding reflexes are, on the contrary, lowered, while the other symptoms, here absent, occur with more or less frequency.

Such and similar points of discrimination would, however, in view of the very limited number of known cases from which to draw conclusions, hardly warrant confidence in an attempt at differential diagnosis.

HYDROCHLORATE OF COCAINE AS A LOCAL ANÆSTHETIC IN GYNECOLOGY.

By W. M. POLK, M.D.,

NEW YORK.

As a matter of some interest, just at this time, I give the results obtained with hydrochlorate of cocaine in two cases of trachelorrhaphy done this afternoon (October 29, 1884).

Case I. *Double laceration of the cervix uteri, extending on both sides to cervico-vaginal junction.*—The vagina was first washed with a warm water douche, then the cervix, the patulous cervical canal, and the vaginal walls adjoining the cervix were carefully washed with Castile soap, this in turn was washed off, and the surface carefully dried. Next a four per cent. solution was painted over the cervix, in the canal, and over the adjacent vaginal wall with a camel's-hair brush. This was repeated twice, at intervals of two to three minutes, making three applications of the drug. Within three minutes of the last application the operation was begun.

It required the removal of extensive pieces of cicatricial tissue from each angle, making it an elaborate operation of its kind. The time consumed was about forty minutes, the patient made no complaint and suffered no pain till the last ten minutes of the procedure, then she spoke of her discomfort as being a sense of soreness rather than acute pain.

Thinking that the case might be one of those in which the normal sensitiveness of the region was not great, consequently one that might have borne the operation without the use of any anæsthetic, local or general, I chose a second.

Case II.—The woman was one having less self-control than the first, and with a good deal of normal sensitiveness about the uterus and vagina. The preparation of the region and the application of the anæsthetic was the same as in Case I.

No pain was felt till the lapse of about twenty minutes, then it was so acute as to require an application of the solution of cocaine, making in her the fourth. In three minutes the operation was continued and soon completed without further pain. This last application was made directly to the cut surfaces, first freeing them from blood.

The patient, who three years ago had had the same operation performed under ether, was asked which method she preferred, that with ether or this last without; she promptly replied, this last.

In the first case the effect of the drug seemed to be, that it not only blunted sensibility, but it appeared to retard the first appearance of blood upon the cut surface.

These cases I offer as a contribution to the solution of the question now so prominently before the profession—the place to be held by hydrochlorate of cocaine as a local anæsthetic. With a view of testing its value in obstetric practice a series of observations are being made in the Emergency Hospital, the solution being applied to the cervix and upper part of the vagina during the severe pains of the first stage of labor. The result I beg leave to communicate to you when the number of cases are large enough to make the report valuable.

Hypodermoclysis is the name given to the process of injecting saline solutions subcutaneously. It has been employed in Naples in the algid stage of cholera, and with some success.

Progress of Medical Science.

Hernia of the Lung.—Dr. Mariani reports in the *Revista de Medicina y Cirurgia Prácticas* the case of a man, forty-five years of age, of good general health, in whom nothing abnormal was discoverable when he was resting quietly. But when he was exercising actively or coughing, a globular swelling appeared in the right supra-clavicular region, varying in size with each respiratory movement. During an attack of violent coughing it would grow to such a size as to pass entirely across the front part of the neck, attaining a volume equal to that of the head. Upon the cessation of the provoking cause, the neck would return to its normal dimensions. This phenomenon was first noticed when the patient was fourteen years of age. The diagnosis was made by Dr. Bellida of a conical hernia of the lung.

Dilatation of the Stomach in Children.—In an article with this title in the *Archives Générales de Médecine* of August and September, 1884, Dr. J. Comby asserts that the affection is one of by no means rare occurrence in young children, and he cites in proof of his assertion upward of fifty cases seen by him in dispensary practice. Dilatation of the stomach, he says, is constantly associated with rachitis, and this is not a chance occurrence, but the relation between the two conditions is one of cause and effect. The digestive troubles precede and prepare the way for rickets, but are themselves the result of improper alimentation. The physical signs of gastric ectasis are a prominent belly, tympanism, and the succussion sound. The functional troubles accompanying this condition are manifold. There may be dyspepsia, convulsions, insomnia, urticaria, eczema, bronchitis, etc., any one alone or several occurring together. The prognosis is serious, because the dilatation may persist up to the period of adolescence or even into adult life. The sole cause of this affection is the improper feeding of infants; the little patients are brought up on the bottle, given solid food prematurely, or weaned at an early period. But the disease may also occur in infants at the breast, who are nursed too much or too frequently. The prophylaxis consists in nursing at the breast and in restricting the periods of suckling within reasonable limits. Weaning should not be begun too soon, and should be accompanied very gradually. When dilatation exists the diet should be strictly confined to milk for infants and dry food for children of a more advanced age. Sometimes washing out of the stomach is necessary.

Aural Thermometry.—Dr. Flitner (*St. Petersburger Dissertation*) has instituted a series of measurements of the temperature of the meatus auditorius, both in health and in acute and chronic ear affections. The measurements were taken by means of a specially adapted thermometer. The average temperature of the meatus was found to be in health 98.4° F., the averages for the axilla and rectum being at the same time about 99° F. The author's general conclusions are: 1. Daily measurements of the temperature in the course of inflammations of the ear show that the temperature of the latter stands in a constant regular connection with the general temperature of the body. Therefore, in ear affections, the local measurements not only may be substituted for, but even must be preferred to measurements of the temperature in the rectum and axilla. 2. The same may be asserted in regard to ear affections complicated with pneumonia, erysipelas, and other diseases. 3. In cases of ear affections complicated with morbid processes in the cranial cavity, or even on the surface of the skull (caries, phlebitis of the sinuses, erysipelas), the temperature in the meatus sometimes stands higher than in the rectum. Hence the measurements in the ear canal give us a clearer indication as to the course of morbid process in the head than the rectal measurements, and are preferable to the latter beyond any comparison.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, November 1, 1884.

CURIOSITIES OF MEDICAL ADVERTISING.

"Nay we see the weakness and credulity of men is such, as they will often prefer a mountebank or witch before a learned physician."
—LORD BACON.

We have been furnished with some instructive facts regarding the extent and character of the quack advertisements which form so picturesque a feature in the daily papers of our country. We refer now only to the personal advertisements of learned gentlemen who announce "advice free," "no cure no pay," "twenty years' Prussian hospital experience," and similar appeals to the business instinct and personal confidence of the community. The American press furnishes a rich field for the study of this kind of literature, a study which is by no means without profit, since advertising columns, after all, reflect the wants of the people. Give us the medical advertisements of a nation and we can get no inconsiderable insight into its character.

One of the first things which strikes the mind in perusing the modest announcements of professional skill set forth in the daily press is the aptness and vigor of the literary style. Here for example is a whole story in three words: "Dr. A. W. X., pile specialist, Indianapolis;" again, "Dr. Tool, removes worms with agreeable remedies, Philadelphia." With more circumlocution a Dr. N. B. announces, "after years of practice" that "married ladies, although apparently healthy and not blessed with offspring, can receive a medicine that is pleasant, safe, and certain to crown their hopes. Let no false modesty prevent your calling." Per contra, another announcement informs the lady readers of the precious press with a suggestive brevity that "our pennyroyal pills are as good as gold."

It is not always in simple language, however, that the specialists of the secular and religious papers present their claims. Assurances of skill and experience, guarantees of success, sympathetic appeals to sufferers from, alas! "Our National Weakness" (which we had always thought was tea) all these are put forth with gorgeous rhetorical embellishments. We might here express the wonder how it is that the East Indian missionary, who "supplies a simple vegetable formula" for cancer, consumption, and erring but noble young men, continues to hold out so long; and why it is that "twenty years' experience in a Prussian hospital" is the necessary qualification for the treatment (by mail) of *amour blessé*.

We desire to do no violence to the feelings of our Western colleagues, but the hard fact exists that the medical advertiser flourishes with an ever-increasing exuberance as we go toward the setting sun. He also develops an originality of expression and fertility of adjective which is hardly known in the South or East.

From Jackson, Michigan, there comes a two column ejaculation of the merits of a local doctor beginning: "Earthquake! Earthquake! Earthquake!" . . . "I will treat on the weekly instalment plan. . . . I can treat the mother, I can treat the father, I can treat the daughter! . . . I will make you a Good Reliable Family Physician!" for twenty-five cents a week.

There is a place in Idaho known as Boise City. Two columns or thereabouts of its local paper are devoted to the advertisements of cock-sure specialists, and private dispensaries, where the erring young and the prematurely old are guaranteed a cure. If it is true that Boise City is but a sample of other Western towns we can only conclude that the amount of "manhood" lost or mislaid in the territories is appalling.

It appears to be the custom of these advertising specialists to make their homes in the great cities and then placard the columns of provincial newspapers with their advertisements. San Francisco, St. Louis, Denver, Chicago, New York, Philadelphia, and Boston are all more or less supplied with these creatures, San Francisco heading the list.

Another custom which is growing rapidly in the West is that of establishing private dispensaries for the cure of all forms of ailment. The Oxygen Cure Company and the Galenic Institute of Minnesota, the Li-po-tai Chinese Sanitarium of San Francisco, the Medical and Surgical Infirmaries in Nebraska, Wisconsin, and Colorado are specimens of this form of enterprise. A somewhat cursory examination among the papers of a dozen Western cities shows that all are supplied with from one to five advertising "private dispensaries." Omaha is blessed with three, and San Francisco with five.

Men and women apply to advertising quacks, first, because they ignorantly believe in their pretensions; second, because they have some disease which they do not wish to disclose to their family physician or a respectable medical man; and lastly, quacks are a final resort of chronic invalidism or fatal disease. The quacks themselves advertise to treat and cure those diseases into whose therapeutics the element of imagination largely enters. "Chronic nervous diseases," sexual disorders, syphilis, all these furnish a fruitful field for presumptuous ignorance to work upon. Among over fifty quack advertisements nearly forty appeal to the classes above mentioned. For the rest, it seems that piles and fistulas, cancer and consumption, varicocele, rheumatism, and gout are paying specialties. In a certain section of the West a Dr. C., "after twenty years' practice in Utah," "will visit Southern settlements, treating club-foot, hare-lip, etc." From which it appears that Utah has advantages for the training of orthopœdic specialists not heretofore generally known.

There is some tendency to make homœopathy a basis of trade. A doctor in Austin, Texas, announces himself as a homœopath, and adds, with a slight degree of orthographical inadequacy, that he makes "difficult and chronic

diseases a specialty." He is less liberal than a certain "specialist of New York City," temporarily residing among the Mormons, whose methods of treatment are stated with an absolute absence of bias, to be "Homœopathic, eclectic, electricity, and magnetism; cures guaranteed by mail," which, we would add, is by far the safest way to guarantee them.

It must not be inferred that the East or South is entirely free from the obnoxious advertisements of the kind we are describing. New York, while it has not many of the typical advertising specialists, is particularly rich in "magnetic healers," "vitalizing rubbers," and doctresses who "take confinements at the house." Throughout New England the practice is gaining of a doctor publishing his card, often with some slight recommendation, such as "graduate of ——," "four years' city experience," etc., appended. By this means good physicians sometimes get in bad company. Thus the card of a Hartford physician comes out sandwiched between that of a clairvoyant and a chronic disease specialist. Certain parts of New England are victimized by itinerant quacks, who enter a town, buy up the local editor, and fleece the hypochondriacs and incurables annually.

We cannot close without referring to an advertisement which recently appeared in the *Philadelphia Ledger*. The capacity shown therein for exact and clear-cut definition of the author's wants and talents is quite unique. A physician, graduate of Jefferson Medical College (Class of ?), "whose religious character is above reproach wants a cash salary . . . in a wealthy sickly family. Warrants to treat successfully dropsy, consumption, cancer," etc. A cash salary in a wealthy sickly family is a great desideratum, and it is unfortunate that society is so arranged that wealthy families as a rule refuse to be sickly; while sickly families as a rule are bound to be poor.

It would be a mistake to infer from the facts and comments given above, that the practice of advertising in the secular press is at all common among the profession in this country. On the contrary, we have been surprised and pleased to find that among the seventy thousand doctors in this country where advertising is a national institution, so few comparatively indulge in it. That the practice is somewhat increasing, however, cannot be denied. And we fear that the license given by a wrong interpretation of good ethical rules, to distribute professional and "practice limited" cards *ad libitum* is doing something to increase this tendency.

THE MEDICAL VALUE OF THE COFFEE ALKALOID AND ITS ALLIES.

There is one element of uncertainty in medical practice which doctors ought to eliminate, and that is the use of impure drugs. No one has done greater service to the profession in this line than Dr. E. R. Squibb, and it has again to thank him for calling in question the utility of certain preparations which have of late years been flooding the market, viz., those of coca and guarana. Dr. Squibb states emphatically that no good, fresh, carefully prepared specimens of coca are obtainable. He also says that the specimens of guarana, which is not a pure article but a South American secret mixture, are also untrustworthy, unequal, and expensive. He has, therefore, decided to abandon the preparation of these articles and to substitute fluid extracts of tea and of green coffee in their place.

It is known that the active principles caffeine, theine, and guaranine are chemically and physiologically identical.

From certain tests Dr. Squibb concludes that, in the power of keeping off drowsiness and producing a sense of restfulness, the following were the equivalents:

Three grains of artificial caffeine = 180 grains of coca, or 45 grains of cocaine; three grains of artificial caffeine = 70 grains of tea, containing 2 grains of theine; three grains of artificial caffeine = 60 grains of guarana, containing 2.6 grains of guaranine; three grains of artificial caffeine = 160 grains of coffee, containing 1.95 grain of caffeine.

According to this the cocaine alkaloid is the strongest, next comes the coffee alkaloid, then that of the tea and of guarana. The differences between the last three, however, are slight and might easily be accounted for, without having to assume any physiological difference in the alkaloids.

The conclusion arrived at by Dr. Squibb is that we can dispense entirely with coca and guarana in medicine, and can use instead officinal preparations of tea and coffee or the alkaloid caffeine. Fluid extracts are preferred, because in this way the dosage can be more accurately adjusted.

Dr. Squibb's views and conclusions merit the attention of the profession, but they are open to criticism in two directions. In offering the tea and coffee extracts as substitutes for coca, guarana, and in a measure, caffeine, he based his inferences as to equivalence mainly upon a series of experiments upon a single symptom, drowsiness, in a single individual. Furthermore, it is to be inferred that cocaine and caffeine are identical alkaloids. This is not the case. The chemical formulæ for the two are different, and physiological experiments, so far as they have been carried, also show some differences in action.

The claim that tea and coffee extracts will do all that coca and guarana will is a plausible one, and it is important that it should be definitely established or refuted. We trust that further careful experiment will be made. Meanwhile we remind our readers of the very truthful words of Rossbach: "The medicinal use of caffeine is very limited."

A NEW BISMUTH-TEST FOR SUGAR.

The Trommer test for sugar is, as all urologists are aware, inexact and difficult in many cases on account of various substances which react with the solution, as creatinine and uric acid, and also because creatinine and other substances retain the cupric oxide in solution. In order to avoid these difficulties it has been attempted to replace the solution by the reduction of subnitrate of bismuth in the presence of an alkaline liquid. To this end Almen has used a solution of 2 grms. of subnitrate of bismuth, 4 grms. of tartrate of potassium and sodium, and 100 grms. of a solution of caustic potash; and with this he has succeeded in detecting 0.1 of sugar in 100 grms. of the liquid.

After a good deal of experimentation on this subject, Nylander, in a recent paper in the *Zeitschrift für phys-*

iologische Chemie, advises a solution containing 2 grms. of subnitrate of bismuth, 4 grms. of the tartrate of potassium and sodium, and 100 grms. of caustic alkaline lessive; the undissolved bismuth salt is separated by filtration, and in order to better determine the effect of the quantity of the caustic alkali, he dissolved in the alkaline liquid 3, 6, 7, 12, and 17 per cent. of supposed anhydrous caustic soda. He found that the solution containing about 8 per cent. of the caustic alkali was much the most delicate, and that it should be used 1 part for 10 of the liquid to be analyzed; also that with this he could easily detect 0.04 per cent. of sugar in the urine. Even with 0.025 per cent. the reaction was not doubtful.

It has been objected to the bismuth solution that it gives a black precipitate, but Nylander shows that this may be avoided by using not more than 8 per cent. of the alkali solution, the precipitate being caused by an excess of it. It does, however, cause a precipitation of phosphates. In examining one hundred specimens of urine fourteen were found, by the bismuth test, to contain sugar. These fourteen were then examined by the Trommer and Worm-Müller methods; these showed sugar in twelve specimens, the result in the other two being doubtful, but the yeast test showed that these also contained sugar. The presence of albumen in a specimen of urine interferes with the reaction of the bismuth solution, but only when it exceeds 0.5 per cent. The presence of sugar is shown by a black or grayish tint. With this test, therefore, as with others, it is necessary first to free the urine from albumen. A great advantage of this solution is that it keeps well.

BRAIN-PRESSURE IN PUBLIC SCHOOLS.

Only a short time ago certain English sanitarians were claiming that the decreased death-rate in Great Britain was largely due to the improvement in the modes of rearing and educating children. Now comes an elaborate report made by Dr. Crichton Brown, in which it is contended that the system of school education in England, is doing great mental and physical damage to the rising generations. He claims that in some London schools nearly one-half (46 per cent.) the children suffer from habitual headache, that 54 per cent. suffer from neuralgia or toothache, 40 per. cent. from insomnia, and that short-sightedness gradually increases from 2½ per cent. in Standard I. to 9 per cent. in Standard VI.

Dr. Brown shows that while in late years the mortality from hydrocephalus under five years of age has been steadily falling, owing to improved sanitary conditions, the mortality between five to twenty years has been steadily increasing. He claims that the cause of this increased mortality is the brain-excitement and fatigue associated with the processes of education. The increase in the number of suicides, especially of those under sixteen years of age, and the increase of insanity are referred to as having some connection with the educational methods.

The main point which is made against the British system of elementary education is, that it attempts to enforce the same amount and kind of instruction upon children who differ in the greatest degree as to mental development and physical strength. The grade system, as carried on, is a kind of Procrustean bed, to which youthful minds must be made to accommodate themselves. Examinations, studying after school and at home, are all sources of immense injury and evil, according to Dr. Brown.

The report, of which the foregoing are the main features, is accompanied with a counter-report by one of the officers of the Government, Mr. Fitch. This latter gentleman vigorously and ably criticises Dr. Brown's facts, conclusions, and methods.

The London medical press naturally supports the medical view of the case, as presented by the distinguished Superintendent of the West Riding Lunatic Asylum.

From this side of the Atlantic it appears as if Dr. Brown had made a very strong plea, but had been rather carried away by the dominance of preconceived convictions. This indeed is not the first time that he has exhibited his capacity for employing tempestuous argumentation and unscientific method. It seems incredible that in the present case he has not made some mistakes. The code exacted by the English school system is lighter than that of France, Germany, Belgium, and, we believe, America. Yet we are told that half of the English school children have continual headaches, insomnia, and neuralgia! Is it brain-pressure that does all this? Then English children must be phenomenally stupid, since there is certainly no such condition in other countries.

The fact is, Dr. Brown has dealt with only half the truth. He should have said more about the homes and food of the school children. Feed them, clothe them, and house them better, and the talk about over-pressure will be very much less.

Not that we deny the existence, to a considerable extent, of the evils depicted. They are known in this country as well as England, and the "Procrustean bed system of teaching" has been condemned for years. But remedies are expensive. The plan suggested of having medical inspectors for the schools is a good one, so far as it goes. It has been tried in France, and in some parts of this country, and has, we believe, worked satisfactorily.

AMERICAN MODE OF USING IODIDE OF POTASSIUM.

For over fifteen years, says Dr. E. C. Seguin, in the *Archives of Medicine*, the practice of giving very large doses of potassium iodide in certain cases has been in use in a small circle of New York physicians. By large doses is meant such as make up a total of two and a half to ten grammes, in twenty-four hours. The cases where these doses are indicated are those of chronic or subacute ulcerative syphilides or of nervous syphilis; in rapidly extending syphilitic ulcer; in extremely acute syphilitic cranial pain; in syphilitic coma or stupor; in certain cases of syphilitic hemispasm, monospasm, or hemiplegia. The mode of administration is to give the saturated solution of potassium iodide largely diluted in plain or feebly alkaline water. It is usually given after meals, and probably, as a rule, acts better in this way. Dr. Seguin advises administering it before meals; and undoubtedly sometimes this method is better. It is one which used to be strongly recommended by older teachers, on theoretical grounds. It is sometimes found, we would add, that the iodide can be best taken in one large dose at night; or, if the potassium salt causes irritability, the iodide of sodium may be substituted.

It should not be forgotten that in a few cases the patients cannot take these large doses, and also that a very prolonged use of them is sure eventually to produce an atonic state of the gastro-intestinal musculature.

Dr. Seguin has quoted a long list of authorities on syphilis, general medicine, and therapeutics, in order to show that the plan of heroic dosage here referred to receives slight or no adequate notice in text-books. It is only in the works of Loomis, Bartholow, and of Van Buren and Keyes, Bumstead and Taylor in this country, and of Buzzard abroad, that any recognition of it is found.

The writer also shows that the method originated with the late Dr. Van Buren, of this city, and became gradually adopted as the result of practical experience by a number of New York physicians. It has been taught by Dr. Wm. H. Draper, by Dr. R. W. Taylor, and also by Dr. Wm. A. Hammond, for many years. It is essentially an American, and more essentially a New York, idea. It is very proper that attention has been called to what is undoubtedly a remarkably efficient therapeutic measure, and that due credit has been given to American medicine for originating it.

News of the Week.

Cocaine Hydrochlorate as a Local Anæsthetic in Gynecology.—Professor Polk, of this city, as will be seen by a communication in the present issue, has used hydrochlorate of cocaine successfully in two operations upon the cervix uteri. The results in these cases look toward an extensive usefulness of the new anæsthetic not only in gynecology but in many of the minor surgical operations.

The Profits of the International Health Exhibition.—The Health Exhibition which was lately closed in London shows a profit of £30,000.

Dr. Joseph White, of Canajoharie, N. Y., died on October 27th, in the eighty-fourth year of his age. He was one of the oldest physicians, and was the oldest Mason in the State.

The International Collective Investigation.—The first inquiry which the Committee propose to institute is in regard to rachitis, its frequency, and the physical condition of the district in which it is found.

The Price of Cocaine Hydrochlorate. — The first preparations of cocaine hydrochlorate used in this city were procured at an expense of 60 cents a grain, or $12 an ounce for a four per cent. solution. It will probably be soon about forty cents a grain. Its price, from present indications, cannot become much less, as only 0.01 to 0.02 per cent. of cocaine can be extracted from the erythroxylon coca, depending on the quality of the leaves. The salt used in Albany at Dr. Merrill's college clinic cost $4.20 per ounce, or 87½ cents a grain. On the other hand, it may not be generally known that Merck, whose laboratory prepared the first used in this city, has an agency in New York, which receives by cable early word of the exportation of special drugs, and that a considerable quantity is now under way to New York. At the principal druggists here the demand has far exceeded the supply. It is to be hoped that the new importation will bring the drug within easy reach of all. It had been used on the continent in throat clinics several months before its introduction into ophthalmic practice by Dr. Koller, which was at the annual Ophthalmological Congress in Heidelberg, September 15th. We learn from a professional friend, living in our vicinity, that he had used it in a case of paræsthesia of the larynx of an exceedingly nervous lady some weeks before the publication of Dr. Noyes' letter in The Medical Record.

Another War over Listerism and Ovariotomy.—A lively discussion is threatened between Mr. Lawson Tait and Mr. Knowsley Thornton upon the question of the value of Listerism in ovariotomy. Mr. Thornton has published a letter (*American Journal of Obstetrics*), in which he tries to show that his own records of Listerian ovariotomies are better than those of either Bantock or Tait, who do not use Listerism. The following tables are interesting:

	Cases.	Died.	Mortality per cent.
Thornton, non-antiseptic hospital ovariotomies	33	5	15.15
Bantock, non-antiseptic hospital ovariotomies	36	8	22.22
Thornton, "Listerian" hospital ovariotomies	129	15	11.62
Bantock, "Listerian" hospital ovariotomies	113	16	14.15
Tait's "strictly Listerian," on his statement	50	3	6
Non-antiseptic	176	24	13.95

It is known that Mr. Tait, when still a rising ovariotomist, was hardly treated with fairness by the London gentlemen whom he now in his triumph too rancorously assails.

The Decline of Antipyresis.—At the meeting of the German Society of Naturalists and Physicians in September last, Professor Ebstein, of Göttingen, read a paper upon the treatment of typhoid fever, based on the treatment of 235 cases in the past seven and a half years. The mortality was 5.5 per cent., or excluding cases where treatment had not been applied, 2.5 per cent. Professor Ebstein denied the value of the abortive calomel treatment. He had used careful dietetic and symptomatic treatment. Baths and antipyretic medicines were only to be used when the high prolonged temperature was evidently causing bad symptoms. The routine use of these measures was not advised. Professor Ebstein's views were supported by most of the speakers in the discussion which followed.

The Recognition of Hard Preliminary Work.—*A propos* of this matter, which we discussed in our editorial columns recently, is a letter from a correspondent of the *College and Clinical Record*, who says: "Men who have worked their way through a good medical school, and passed the ordeal of spiking the masked battery they were compelled to charge at the end of their collegiate course, feel that they have learned something substantial, and that their diplomas are the certificates to this effect made by illustrious men. Every honest worker feels this; and even though he know enough to know how little he knows, yet he feels that his diploma is worth more than that of a man who graduated at the 'College of Physicians and Surgeons of Brown's Cross Roads, Western Arizona.' It is true, a good diploma does not

make a good doctor, but it immensely increases the chances in this direction, and diplomas do have a varying commercial value!" A self-protection, the writer adds, will drive all graduates of first-class colleges to the plan of indicating their alma mater after the letters M.D.

The correspondent from whom we quote is right, so far as he goes. As is natural with young graduates, he attaches a rather exclusive importance to the value of his alma mater, and forgets that other things than two or three years at a medical college are required to make a doctor. The degree of A.B. or A.M., the year or more in a hospital, the post-graduate study abroad or at home, may, any one of them, more than compensate for didactic disadvantages.

The Use of Cocaine Hydrochlorate by Dr. E. S. Peck, of New York.—Dr. Peck writes: "Of the three uses of the drug—one physiological, two clinical—at my hands, only one deserves special mention at this time, while all corroborate its anæsthetic properties. A laborer received a clean wound of the lower lid, cutting through the conjunctiva, tarsal margin, and integument. A stitch in the conjunctiva and two in the integument of the lid were taken after six instillations of a four per cent. solution, covering twenty-five minutes. Patient experienced no pain either from the forceps or needles, and stated that the sensation was as if something had been pressed against the parts involved."

The Shady Side of Medical Education Abroad.—The New York *Medical Journal* discusses in a forcible and suggestive manner certain of the dangers to which students who go abroad to study for medical instruction are subjected. "We have no hesitation in asserting," says the *Journal*, "that many a medical student who would have made a steady and honorable member of his profession, had he entered upon his duties at once on leaving college or hospital, has been spoiled by his residence abroad, where he has broadened his professional knowledge but suffered an irreparable loss of moral tone, in delicacy of feeling, and in tenderness toward suffering. This is no cant—it is simply an every-day experience. It is unnecessary to urge the trite remark that an educated physician is something more than an encyclopædia of facts or an infallible diagnostician, that he is or should be an honorable gentleman, and that, too, not for utilitarian reasons, but because it is *in him*. . . . The 'free and easy' moral atmosphere of the great continental capitals, notably Vienna, the light regard in which woman is held, the perfect subjection in which patients are kept, and the cold-blooded way in which those patients are treated—all of these are dangerous elements in foreign medical education. . . . Again, methods of examination and treating patients are learned which it would be positive professional suicide for a man to practise at home." There is more in this same line given by our esteemed contemporary, who does not at all deny at the same time that great benefit may be obtained by foreign study. We commend the remarks to those of our readers who contemplate studying abroad or sending their sons there. It is true that the profession has now more need of honorable gentlemen than of "soulless scientists" in its ranks.

The Paris Academie de Medécine has talked cholera all summer and has got no further on the matter than when it started. Upon great occasions this learned body seems always to turn itself into a Cave of the Winds.

Dr. Mills succeeds Dr. Osler as Professor of Physiology in the McGill Medical College, Montreal.

Poisoning from Mother Winslow's Soothing Syrup.—Dr. A. B. Hirsh reported to the Philadelphia County Medical Society the case of a boy, aged twenty months, who was poisoned by "Mother Winslow's Soothing Syrup." He was given four doses of less than half a teaspoonful in fourteen hours. Vigorous anti-narcotic treatment alone saved the child. Many physicians, we believe, are familiar with similar cases.

American Academy of Medicine.—At the annual meeting of the American Academy of Medicine, held this week in Baltimore, the following officers were elected: *President*—Albert L. Gihon, United States Navy; *Vice-Presidents*—R. Stansbury Sutton, of Pittsburg, Pa.; James A. Steward, of Baltimore, Md.; William Elmer, of Bridgeton, N. J., and James Cheston Morris, of Philadelphia, Pa.; *Secretary and Treasurer*—Richard J. Dunglison, of Philadelphia, Pa., and Charles McIntyre, Jr, of Easton, Pa., *Assistant*.

Dr. Oliver Wendell Holmes, of Boston, and Major George M. Sternberg, M.D., of the U. S. Army, were elected honorary members. The following resolution was unanimously adopted:

"That the American Academy of Medicine recognizes in the recent munificent gift of William H. Vanderbilt to the College of Physicians and Surgeons of New York, a most important and valuable service to the science of medicine in America; that in this spirit the Academy tenders to Mr. Vanderbilt its obligations, with the assurance that in no better way could the higher education of our profession and the benefit of humanity be promoted."

Reviews and Notices.

The Alpine Winter Cure. With Notes on Davos Platz, Wiesen, St. Moritz, and the Maloja. By A. T. Tucker Wise, M.D., L.R.C.P., M.R.C.S. London: Baillière, Tindall & Cox. 1884.

Dr. Wise has made a special study of certain mountain health-stations, and, writing without bias or exaggeration of any kind, what he says may be accepted as true without hesitancy. The remarkable curative and health-giving properties of the Alpine climate are abundantly shown in this unpretentious little volume.

Practical Manual of Obstetrics. By E. Verrier, M.D., Lecturer on Obstetrics in the Faculty of Medicine of Paris. Fourth Edition, with the Four Obstetric Tables of Professor Pajot; One Hundred and Five Illustrations. First American Edition, with Revision and Annotations by Edward L. Partridge, M.D., Professor of Obstetrics in the New York Post-Graduate Medical School. Wood's Library of Medical Authors. New York: W. Wood & Co. 1884.

This is a brief *résumé* of practical obstetrics, more particularly from the French point of view. It has been in a measure Americanized by the incorporation of more or less important notes supplied by Dr. Partridge. In its new shape it will be found serviceable by students and those practitioners who lack time for the study of certain details, which are necessarily found in the more pretentious and elaborate treatises.

STUDENTS' MANUAL OF ELECTRO-THERAPEUTICS. By R. W. AMIDON, A.M., M.D. New York: G. P. Putnam's Sons. 1884.

THIS modest little volume can in no way replace, nor does it pretend to, the more elaborate treatises on medical electricity already extant. But as an introduction to practical electro-therapeutics this book has its *raison d'être*. Its chief merit consists in the fact that it is quite concise, and, as far as it goes, thoroughly scientific. Static electricity is not dignified by so much as a mere mention by the author.

MALARIA AND MALARIAL DISEASES. By GEORGE M. STERNBERG, M.D., F.R.M.S., Major and Surgeon U. S. Army, etc. Wood's Library of Medical Authors. New York: W. Wood & Co. 1884.

THE author has wisely prepared a work which will be very welcome to the general practitioner, as giving, not the dogmatic views of a single person, but the combined experience of observers in various countries, including, of course, our own. It is obvious to all candid minds that there are many puzzling problems connected with the subject of malaria. Dr. Sternberg does not pretend to have solved them. On the other hand, we certainly know considerably more about malarial diseases to-day than we did ten or even five years ago. The author's treatise is in the main an able and candid review of the actual state of our knowledge, considered in the light of the most recent researches published at home and abroad, supplemented by the additional information derived from the author's personal studies.

MANUAL OF PHYSIOLOGY. By GERALD F. YEO, M.D., F.R.C.S., Professor of Physiology in Kings College, London, etc. Philadelphia: P. Blakiston. 1884.

THIS is an elementary treatise designed for the use of students. It is clearly written, and, while not too bulky a volume, it yet contains all the facts necessary to a comprehension of the principles of physiology. The style is much simpler than that of Foster's well-known treatise, and there is far less display of abstruse science. Yeo's physiology does not commend itself to advanced students, but the beginner will find in it all that he needs for the acquisition of clear ideas concerning the first principles of a rather complicated science.

THE HUMAN ELEMENT IN SEX. Being a Medical Inquiry into the Relation of Sexual Physiology to Christian Morality. By DR. ELIZABETH BLACKWELL. Second Edition. London: J. & A. Churchill. 1884.

THIS little work, though a trifle diffuse in style, and perhaps a little narrow in some of its positions, is on the whole a sound, sensible, and useful contribution to the subject of physiology and morals.

Reports of Societies.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Annual Meeting, October 27, 1884.

S. OAKLEY VANDER POEL, M.D., LL.D., PRESIDENT, IN THE CHAIR.

THE REPORT OF THE BOARD OF CENSORS,

together with the report of the counsel of the Society, E. C. Ripley, Esq., was read by Dr. J. W. Howe, Secretary, and showed that during the last year the work of prosecuting illegal practitioners had been carried on vigorously and successfully. The Eclectic Medical College of the City of New York had been proceeded against for illegal transactions with reference to granting diplomas, and the prospect was clear for convicting the authorities of the institution of having issued bogus diplomas, and therefore the annulling of the charter of the college.

THE REPORT OF THE COMMITTEE ON ETHICS showed that charges made by one member against another had occurred in only one instance, and in this the plaintiff had declined to press them.

The committee spoke against the indulgence to which physicians, to a considerable extent, favored themselves with, by recommending copyrighted medicines, mineral waters, etc.

THE REPORT OF THE COMMITTEE ON HYGIENE was read by Dr. R. Van Santvoord, Secretary, and consisted of two parts: First,

VENTILATION OF THE SEWERS,

by DR. E. H. JANES. "Among the reports presented by the Committee on Hygiene at the last annual meeting was one reflecting somewhat severely on the method of ventilating public sewers in this city. This subject, regarded by your committee as an important one, has received considerable attention, and while the method of ventilation now in use may be open to criticism, and in some localities decidedly objectionable, the present committee is not yet prepared to fully sustain the report of its predecessor, nor to suggest any other plan that would be equally practicable and as readily controlled by the public authorities.

"The principal object of sewer ventilation is to protect the atmosphere of our dwellings from what is commonly called 'sewer gas,' or, what it is more properly, sewer air, with which is mingled more or less of the products of organic decomposition. Its necessity arises from various causes to which sewers are exposed. Variations in temperature, the amount of sewage, efficiency of flushing, rate of flow, and condition of the outlet, all influence the development of deleterious gases, as they retard or hasten the process of decomposition, and thus bear an important relation to the necessity for ventilation. A sewer with a uniform water supply and a steady, uninterrupted flow will require less means for ventilation than one which is tide-locked twice every twenty-four hours, and thus subjected to periodical contraction and expansion of its air capacity. When a sewer becomes tide-locked, not only is the discharge for the time being arrested, but the contents accumulate by reason of fresh contributions of sewage and tidal influx; and if this occurs during a heavy rain the case is aggravated, the accumulations of sewage, tide, and storm-water increase, and the air in the sewer is forced back, being more and more compressed, perhaps to half its original volume. In this condition we have within the sewer the presence of an additional atmosphere which no house-trap can withstand. The method of relieving this pressure adopted in our city, in the city of London, and indeed in all the cities of England, is to perforate the manhole-covers that the imprisoned air may escape along the middle of the roadway, and thus mingling with the atmosphere, the gaseous products of decomposition are readily diffused, the organic particles oxidized and rendered harmless. As the tide recedes the sewer is relieved of its engorgement, the manhole shafts become inlets for fresh air, and thus the air in the sewer is renewed as the accumulated sewage is washed by the receding tide.

"During the period of low water, and also in sewers that do not become tide-locked, the manhole shafts act alternately as upcast and downcast shafts, according to variations of temperature which occur at every discharge of hot water from the house-drain, causing an upward current at one manhole and a downward one at the next. In proportion as the air in the sewer is thus kept in motion, and the flow of sewage is uninterrupted, will decomposition be retarded or prevented, a result secured only by constant motion as opposed to stagnation. It does not appear that the air from such a sewer discharged through the manhole-covers along the roadway of a street lying in the direction of the prevailing winds, can be to any extent injurious to occupants of houses on such a street. With stagnant sewers along narrow, crooked

streets lined on either side with high buildings, the case is different, and often aggravated by the discharge of waste steam into the sewer, a practice which cannot be too severely condemned.

"It appears to your committee that while the dangers arising from ventilating sewers into the roadway have probably been somewhat exaggerated, still a better method would be desirable, could one equally practicable be devised and adopted. It has been suggested that sewer ventilation would be best and most safely effected by carrying a four- or six-inch pipe from each house-drain at a point between the trap and the sewer up the wall of the house so as to terminate above the roof. Were houses along a street of a uniform height, and the material and joints of the ventilating pipe impermeable to sewer air, such a method would be an improvement on the one now in use, but its adoption would involve the interference of the authorities with the rights of private property owners, which our citizens are not yet ready to grant. A far more effective method would be to ventilate through the house-drains and soil-pipes, the warmth of which would maintain a constant upward current, while the perforated manhole-covers would serve as inlets for fresh air. But as this method would require absolute perfection in our plumbing arrangements, a condition which does not obtain in our city, your committee cannot think of recommending it."

The second part was prepared by Dr. Richard H. Derby, and consisted of

NOTES ON CONTAGIOUS OPHTHALMIA IN SOME OF THE ASYLUMS OF NEW YORK CITY.

After giving an outline of the clinical features of this disease, making special reference to its contagious character, the writer directed attention to the existence of the malady among the children cared for in the larger asylums of this city.

In the asylum for boys he found that about twenty-nine per cent. had contagious ophthalmia; in the asylum for girls, nineteen per cent. In nearly all these cases the disease was in the first stage. On inspecting the dormitories and wash-rooms it was found that each child had its own bed, separate towel, and that water for washing was supplied from small jets, at intervals of one foot, along a horizontal pipe above the sink; no basins were used. In the boys' asylum the bath-tub was sufficiently large to allow eight to bathe at the same time.

In another of the largest institutions, 28.5 per cent. of the seniors; thirty-six per cent. of the juvenile department in the boys' division had contagious ophthalmia; in the girls' division thirty per cent. of the seniors were afflicted with the same affection. Total number of children, 1,586.

After giving similar statistics from another institution, Dr. Derby continued that the communicability of the affection was strikingly illustrated by the fact that when a group of children presented themselves in succession, they were those who habitually occupied adjacent seats in the class-room.

The purpose of these investigations will have been effected if the writer succeeded in drawing attention to the fact that in the asylums of this city a disease fraught with danger to the eyes of all assembled there exists to an alarming extent.

The whole number of children examined was 3,025, whose eyes were believed in the main to be healthy, and 25.12 per cent., or one out of every four, had communicable eye disease. To meet an evil so great, should not a commission be appointed by our State Board of Health, for the purpose of making a thorough investigation of the condition of the eyes of all inmates of our asylums and reformatory schools? Should we not see, *first*, that it be an absolute rule in these institutions that no child be received until his or her eyes have been examined by competent men? *Second*, that from time to time the eyes of all inmates of these institutions should be examined, and if cases of contagious ophthalmia are found they should be isolated and receive proper treatment?

For assistance in making these investigations he was indebted to Dr. W. S. Dennett, of this city.

On motion by Dr. C. R. Agnew, the present Committee on Hygiene was continued as a special committee to report further on the subject of Dr. Derby's contribution.

OFFICERS FOR THE ENSUING YEAR.

President, Dr. Daniel Lewis; *Vice-President*, Dr. Laurence Johnson; *Secretary*, Dr. Wesley M. Carpenter; *Assistant Secretary*, Dr. Charles H. Avery; *Treasurer*, Dr. Orlando B. Douglas; *Censors*, Drs. Joseph W. Howe, Frederick R. S. Drake, Francis M. Weld, Henry T. Peirce, William Oliver Moore.

THE COMMITTEE ON PRIZE ESSAYS.

Dr. C. C. Lee, Chairman, reported that only one es say had been submitted, and that in the unanimous opinion of the committee it was not sufficiently meritorious to be entitled to the prize.

THE OFFICE OF CORONER.

Dr. R. Tauszky offered a resolution asking the Society to indorse the nomination of Dr. Messemer for Coroner. It was laid upon the table.

PROPOSED AMENDMENT TO THE BY-LAWS.

Dr. A. Jacobi offered the following amendment to the by-laws. That the *Comitia Minora* be directed to recommend no applicant for admission to membership unless he be a graduate from a medical college in good standing, or a licentiate of a regular—unsectarian—State or County Medical Society of this or any other State; or if his certificate be of sectarian character, unless the applicant declare in writing his or her abnegation of sectarian principles and practice. Laid over under the rule until the next annual meeting.

An amendment to the by-laws was adopted providing that the stated meeting heretofore held in the month of June be omitted.

On motion by Dr. Piffard, the subject of

ARREARS IN DUES

was referred to the *Comitia Minora*, to be reported upon at the next meeting of the Society with reference to the best method of dealing with delinquents.

APPLICANTS FOR MEMBERSHIP GRADUATES OF HOMŒOPATHIC MEDICAL COLLEGES.

The *Comitia Minora*, to which the applications of two candidates for admission to membership have been referred back, because they were graduates of homœopathic medical colleges, reported again, and recommended that certificates of membership be granted to these applicants.

The Secretary read letters from the candidates, in which each stated that he had resigned from all homœopathic medical societies, did not and would not practise medicine with sectarian designation, were in no way connected with homœopathic medical journals, and were willing to be governed professionally by the by-laws and regulations of the Medical Society of the County of New York.

Dr. E. Eliot, by proxy, offered the following motion: That a diploma from a homœopathic medical college alone must not be considered as a claim for admission to membership in this Society.

The motion was laid upon the table, and the recommendation of the *Comitia* was adopted.

The President announced the deaths of Dr. John G. Adams, Dr. Joel Foster, Dr. David F. Fetter, and Dr. Allen S. Church.

The Society then adjourned to meet on the fourth Monday in November.

THE NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, October 7, 1884.

W. J. MORTON, M.D., PRESIDENT, IN THE CHAIR.

ON THE NERVOUS ORIGIN OF SOME DISORDERS OF THE ALIMENTARY CANAL.

DR. L. WEBER read a paper on the above subject (see p. 481).

DR. E. C. SEGUIN, in opening the discussion, said that the disorders alluded to in the paper just read were far from uncommon. It must often prove quite difficult, however, to reach a positive diagnosis. The abdominal symptoms were by no means so characteristic and well-defined that a clear case could readily be made out. It was to be remembered that dyspepsia, pure and simple, was frequently accompanied by a variety of morbid nervous manifestations. In this country especially, where we had both many dyspeptics and numerous neurotics, a differential diagnosis would not always be possible. In this connection he also alluded to the fact that the ordinary American diet and cookery predisposed to gastro-intestinal fermentation. He thought that repeated physical examinations at different periods, even of the same day, might aid in putting a diagnosis on a firmer basis. It was important in all cases to separate subjective sensations from true objective symptoms. The discovery of the tender pressure-points was new to him. He failed to see how hyperæsthesia of the deep-seated abdominal nerve-plexuses could be discovered through palpation. As regarded treatment, he was of opinion that it should be in the first place tentative. From his own experience he was inclined to place more value upon a general tonic *régime* than upon direct and local medication.

DR. LESZYNSKY inquired whether Dr. Weber's patients were also sufferers from migraine, and on being answered in the affirmative as regarded two women, he said that Clifford Allbutt, in the recently delivered Gulstonian Lectures, had laid stress on the frequent association of these evils.

DR. DANA stated that he had failed to find evidence of hyperæsthesia of abdominal ganglia, especially of the gastric plexus, in cases of this kind. In his patients, who were generally quite thin, Dr. Seguin's objections touching the possibility of deciding as to the presence of this symptom by palpation, had not been found to hold good. He had been able to explore the abdomen in its deeper parts very thoroughly in his cases. He pointed out that fermentative dyspepsia might accompany, as an independent affection, various neurotic disturbances, and cited a case forcibly illustrating such a condition. In the treatment of neurotics suffering with pronounced gastric disturbances he had found mountain air beneficial.

DR. PUTNAM-JACOBI thought that one important diagnostic point had been overlooked, namely, the relation of the onset of the paroxysm of pain to the time of eating. In purely nervous dyspepsia, say of reflex ovarian or uterine origin, the symptoms of gastric distress were at their maximum during the hours of fasting, and relief might be procured by the ingestion of food. In fermentative dyspepsia, on the other hand, the introduction of food into the stomach would only aggravate existing symptoms. Moreover, pain occurred from one-half to two hours after a meal. Besides this, the acid eructations, the coated tongue, the bad taste in the mouth at morning, should make differential diagnosis comparatively easy. In nervous dyspepsia the tongue was remarkably clean. During, or even before a paroxysm of pain, nausea was not observed.

Two marked cases of neurotic dyspepsia had fallen under her observation some time ago. The first concerned a lady, sixty years of age, who soon after having come under the influence of London's foggy weather, developed two neuroses. The first was spiritualism, and the second violent paroxysmal gastralgia. Six eminent London physicians decided that she was afflicted with cancer. But Italian sunshine quickly cured her. The second case was that of a man who, after the loss of a loved child, became much depressed in spirits, and was afflicted with gastralgic attacks. For months he grew progressively worse, losing flesh all the time. He was eventually completely cured by arsenic. Another case had been cured by the faradic current. She thought that it was more difficult to distinguish moderate degrees of glandular atrophy of the stomach from neurotic disorders than to separate the latter from fermentative dyspepsia.

DR. H. D. CHAPIN believed that the nervous manifestations were often secondary to acid fermentative processes, set up by the excessive consumption of starchy foods.

DR. E. C. WENDT remarked that it was quite evident from the drift of the present discussion, as well as from similar debates in foreign societies, that the entire subject was still involved in considerable obscurity. One thing was certain, however, namely, that the profession in all civilized countries was beginning to reinstate the nervous system, in its relation to disease-development, into a formerly occupied position of pre-eminence. Not many years ago the pathological school had been so exclusively dominant that functional disorders had been almost relegated to the limbo of the mythical. Within the past few years, however, a great change had set in, and at present there seemed to be, if anything, a danger of falling into the other extreme. Certain it was that to-day there either was much less gastro-intestinal catarrh, or else it was more frequently overlooked than formerly; while on the other hand nervous dyspepsia must either be of much more frequent occurrence, or else be erroneously assumed to exist in true structural disease of the alimentary canal. Clifford Allbutt had, in the recently delivered Gulstonian Lectures, drawn some vivid pictures of this class of cases, and the whole subject had been but lately discussed at the third German Congress of Internal Medicine. At that meeting Leube had reiterated his former well-known views on nervous dyspepsia. But he had been opposed by several competent observers, prominent among whom was Ewald. The latter took the ground that real disease of the stomach might start the entire train of nervous symptoms so often seen in neurotics. Trousseau's *vertige stomacale*, dyspeptic migraine, and Rosenbach's cases of vagus neurosis were some of the rarer manifestations belonging to this category. Ewald further asserted that Leube's well-known *Verdauungs-versuch* had no great practical value, for he had in many instances found food-particles in the water used for washing out the stomach seven hours after a simple meal. So also he had found the gastric fluid in positive structural disease, such as cancer and chronic catarrh, to give normal chemical reactions. Dr. Wendt thought it was quite evident from all this that we still lacked decidedly characteristic or pathognomonic symptoms of this class of disorders. It should never be forgotten that dyspepsia was not a disease in itself, but might be a symptom of very many vastly dissimilar affections. To the presence or absence of painful pressure-points, supposed by Burckart to be characteristic of nervous dyspepsia, he had not, from his own experience, learned to attach any significance. He also thought that the term gastric neurasthenia, suggested by Burckart, was not a happy selection. Such cases should be classified rather under the general heading of "nervous disorders of the alimentary canal." One point he wished, however, to emphasize, namely, that nervous dyspepsia did not kill. He had seen such patients apparently brought to the very door of death, but in the end they had invariably recovered. One case he remembered in particular, that was almost the exact counterpart of the first case mentioned by Dr. Jacobi. Here too, eminent physicians had been misled, probably by the cachectic appearance of the patient, to diagnosticate gastric cancer. But the lady in question fully recovered, and at present, six years after she had been given

up, she was better, stronger, and weighed more than at any other period of her life that she could recollect. Finally, as regarded treatment, he thought that general and hygienic measures were more calculated to benefit sufferers of this class than drugs. Absolute rest was at times imperative. Of drugs he thought arsenic was the best for the intervals, and morphine subcutaneously or in suppositories for paroxysmal pain.

Dr. Morton alluded to the ready supervention of diarrhœa through emotional disturbances in neurasthenics. Animals under excitement often showed similar symptoms, but he did not wish to infer for this reason that they too were afflicted with neuroses.

Dr. Teed, of Kansas City, raised the query whether we were not painting old facts in new colors. He believed that all the troubles mentioned in the paper and the discussion could be included under the old designation of atonic dyspepsia. His explanation of the origin of these disturbances was as follows: Nervous influence that should be sent to the stomach became diverted into other channels, and as a consequence the gastric glands failed to perform their function. Besides this, nerve stimulation might happen in the stomach, be thence transmitted to the central nerve-organs, and once more reflected back upon the stomach. Ingestion might in this way lead to watery secretion and thus result in copious evacuations. But the neurotic taint might manifest its existence through other organs besides the stomach. Cardiac palpitation might occur. The latter might even co-exist with gastric distress and yet the consummation of digestion be neither retarded nor in any other way disturbed.

The great point to know was, where did all the nerve-force come from? How did it originate in the body? In his opinion it ultimately depended entirely upon oxidation or some similar chemical change constantly taking place in organized beings. He thought that the various cells of the body might be likened to minute electric batteries that were perpetually active. Through their agency force was liberated which primarily assumed the form of heat. In this way currents were normally sent to the brain and again started out from the encephalon to other parts.

Of course, if the paths of conduction became altered failure of force-transmission must result. This gave rise to morbid symptoms which we must endeavor to interpret. He also compared the relations of the cerebro-spinal with the sympathetic nervous system to the two wires of a battery. One thing was certain, namely, that new matter or new force had no existence in the human body. The same physical laws that governed the outer world also held good for our bodies. It was essential, therefore, to know well the rules and laws of the transmission and radiation of force in the outer world before we could hope to understand the actual condition of nerve-action within us.

Dr. Weber, in closing the discussion, said that he agreed with Dr. Seguin in the importance which he attached to a thorough examination of cases of dyspepsia of whatever nature, particularly as to the presence of dilatation, but believed that dilatation was not only liable to occur when patients indulged in too liberal quantities of farinaceous food and sweets, but also by the vicious habit which many people, young and old, had of putting much more food into their stomachs at a given meal than the organ ought to receive at one time. Like Dr. Dana, he had not been able thus far to verify Dr. Burckart's experiences as to the tenderness of one or more of the abdominal sympathetic ganglia in certain cases of gastric neurasthenia.

The good results which Dr. Putnam-Jacobi and others had seen from small doses of arsenic in the management of these disorders he was ready to accept as an illustration of rational therapeutics. He had himself seen excellent results from drop-doses of Fowler's solution, taken on an empty stomach, in the early morning retching and vomiting of habitual topers. He believed that Dr. Wendt was right when he said that Dr. Burckart's designation of "neurasthenia gastrica" was not happily chosen, and that the general name of "nervous disorders" would be better.

PSEUDO-BULBAR PARALYSIS.

Dr. William Browning, of Brooklyn, read a paper illustrating the above condition (see p. 487).

Dr. E. C. Seguin related a case of bulbar disease which, if not quite germane to the present subject, was intrinsically so interesting as to merit the notice of the Society.

Male, forty-four years of age, seen January 31, 1876, in consultation with Dr. M. J. Moses. Denies syphilis or recent sore throat. Well up to January 1st, when he had epileptiform attacks limited to the limbs of the left side; in one attack the tongue was bitten. No recurrence of attacks. Subsequently severe right supraorbital neuralgia cured by arsenic. On January 29th sudden inability to swallow solids developed in four or five hours. Examination shows a spasm (?) two inches below pharynx. The voice is nasal and articulation is imperfect. Patient is conscious of the labor of speaking.

In view of the rapid development of the symptoms, I expressed the opinion that the case was not one of true bulbar paralysis of the progressive form, but an acute paralysis due perhaps to an ignored diphtheria, and that the prognosis was not quite hopeless.

On February 7th, nine days after the appearance of dysphagia, Dr. Moses sent the patient back to me with the following letter:

"My Dear Doctor: I asked Mr. S—— to call upon you and deliver this note, which for obvious reasons I send sealed. I am afraid he shows more progressive symptoms than when you last saw him, and that the prognosis made now would not be quite as favorable. I think it will be necessary to put you in possession of all that has happened since last Monday when you first saw him.

"On Monday evening he lost the power of swallowing fluids, and I passed a stomach-tube, but it produced such irritation that he almost suffocated from spasm of the glottis when the tube was in his stomach. I passed the tube several times, but each time was forced to withdraw it to avoid a catastrophe. I finally hit upon an idea which I congratulate myself and the patient upon. Having learned from previous examination that the middle and lower muscles of constriction were not as much involved, I made my patient lie down and permit the mouthful of fluid to flow down below the edge of the velum, and *then* to swallow. This effort raised the larynx and propelled the fluid within the grasp of the lower constrictors. By this device (lying down at each mouthful, with the head thrown far back) Mr. S—— was able to take sufficient nourishment, milk, eggs, and beef-tea, and his medicine, viz., quinine, iron, and strychnia in solution, during yesterday and Wednesday.

"On Tuesday, by violent effort, he was enabled to swallow sitting up, but at the same time I noticed marked loss of power in the muscles of the cheeks and lips, and an aggravation of his nasal speech. I noticed also, steadily progressing, an irritation of the pneumogastrics, evinced by violent, prolonged, and characteristic cough. The irritation is almost constant, touching the throat with an electrode or the effort of swallowing bringing on a most violent paroxysm. I have faradized the muscles of the pharynx with a gently increased current, and galvanized the spinal accessory and glosso-pharyngeal with from four to six cells of Kidder's eighteen-cell battery. At first each was well borne, but yesterday a very mild current from either battery provoked vomiting, and on passing a current from six cells over the pneumogastric, I provoked a prolonged and almost exhaustive cough. I am afraid the disease is progressive and due to central lesion. I send him to you for another examina-

tion, that you may compare his present condition with the result of your examination last Monday, and see if some new points may not have arisen to point to you a separation of the two theories then presenting, viz.: labio-glosso-pharyngeal, or diphtheritic paralysis. . . ."

Examination: speech not as good; whistling is possible but feeble; can't fill cheeks with air; much salivation; orbiculus oris weaker, but can still make O. The tongue moves well in all directions. Voice not as loud as at last note. Much cough (more morning and night). Throat very irritable. No facial palsy (apart from orbic and buccinator paresis). Voice very nasal and articulation is impaired. In speech and by reflex action soft palate acts well. Fails to swallow a morsel of bread, and the laryngoscopic mirror shows it lying behind the glottis a little to the left. Rima glottidis red; vocal cords not seen; no anæsthesia of face or hands; no hemiplegia.

It should be added that two years ago patient had neuralgia of the left side of the face and paralysis of the left vocal cord. Again denies syphilis. I adhered to my diagnosis of acute non-progressive bulbar paralysis, and advised continuing the iron and strychnia and using weak galvanism to back of neck and outside of throat. My notes are not complete, but I can state that the patient recovered somewhat slowly but completely in a few weeks.

Dr. Morton alluded to two cases of hysterical simulation of bulbar disease that had been on the point of being reported as instances of progressive bulbar paralysis, when both recovered completely.

Dr. Seguin said that the converse mistake had once happened to him. It was a case which, owing to the absence, at the first visit, of labial symptoms and the predominance of palatal disturbance, was held to be not a genuine instance of progressive bulbar disease. At the second visit, however, difficulty of swallowing and other signs left no doubt as to the true nature of the affection.

NORTHWESTERN MEDICAL AND SURGICAL SOCIETY OF NEW YORK.

Stated Meeting, April 18, 1884.

E. C. Harwood, M.D., President, in the Chair.

Dr. Edward S. Peck read a paper (see p. 482) on

MINERAL ASTRINGENTS AND CAUSTICS IN OPHTHALMIC PRACTICE.

Dr. Baruch objected to the use of the word *caustic* as implied in the paper, as it was not its usual signification. Caustics and astringents present this great difference, that the former are destructive, and the latter produce their effect without destruction of tissue. In the groups of conjunctivitis alluded to, silver-nitrate should be regarded as an astringent. Silver-nitrate is not a caustic in liquid form; it is not destructive except by violent application. It acts rather as a modifier of the action of disease.

Dr. Page uses tepid water in painful forms of conjunctival inflammation; has been led to believe cold water injurious, and has never used silver-nitrate. He cited a case of recurrent phlyctenular conjunctivitis, which was brought on by overwork at school, and was successfully treated by general treatment with calomel applied locally to the eyes.

Dr. Knapp agreed with the paper in its differentiation as to the selection of caustics, especially the sulphate of copper stick in chronic granular conjunctivitis; but the longer he practises in such diseases the more restricted is his use of caustics. So long as a conjunctivitis is acute, he abstains from powerful remedies; he uses cold compresses day and night. When the disease is in danger of becoming chronic, then he uses caustics and astringents. In the ophthalmia of scrofulous individuals, he has ordered the head to be dipped in pails of cold water, and with very good results. The peculiar form of vernal conjunctivitis brought out in the paper he believed to be endemic in character; no treatment seemed to be of avail. He prefers mild alkaline washes; astringents seem to do no good.

Dr. Bosworth used silver-nitrate only on the mucous patch in throat cases. He has abandoned all solutions of the salt in treatment of throat diseases. Cold water is always an irritant to columnar epithelium.

Dr. Wood thought the hygienic surroundings of patients suffering from granular conjunctivitis were frequently at fault; upon the correction of these depended the success of treatment of such cases. In the ophthalmia of the newly-born, whether simple or gonorrhœal, mild treatment met all requirements. Constant washing out with hot water, and dropping mild alum water into the eye three or four times a day, constituted his treatment in such cases.

Dr. McLaury had used hot water with best effect in similar cases of purulent ophthalmia of infants.

Dr. Jacobus believed the pain which was felt on the application of cold water to a mucous membrane was caused by a swelling and rupture of the epithelium. If salt in the proportion of about one drachm to one pint of water be used, it becomes similar to the physical fluids. In gonorrhœal ophthalmia he uses hot water for cleansing and vaseline to keep the lids apart.

Dr. Agnew premised his remarks by saying that thirty years ago caustics and antiphlogistics were much used in ocular affections. Now he does not use silver-nitrate in any form, either in private or public practice, and copper but a very few times in the course of a year. He relies upon general treatment more and more each year. He believed topical applications had been carried to excess. The cold douche was just the tonic needed in some chronic forms of conjunctival disease. Keeping the parts clean was an important point always to be had in mind. Hot water was now used where formerly cold had been employed. He believed that the highest attention should be paid to tissue-building.

Dr. Jarvis thought the amount of silver-nitrate employed should determine whether its effect was or was not caustic. It acts mechanically by producing an albuminate, thus securing protection to the subjacent parts; this action is chemically astringent. When frequently employed it produces destruction of tissue, and should be regarded as caustic.

Dr. Fruitnight corroborated the statement made by the author of the paper as to the etiology of cases of purulent ophthalmia of the newly-born not being necessarily gonorrhœal; he had seen a number of such cases where the mother was positively free from the disease. He uses in such cases very hot water with alkalies, usually borax, with best effect.

Dr. Knapp further stated that Ernst Henry Weber, physiologist of Leipzig, first introduced the use of cold water in treatment about forty years ago. It was the imbibition of water by the epithelial cells which caused pain during the use of cold water.

The President stated that he uses ice-bags as compresses to the eyelids, and has also used cold as well as hot water as a styptic in ophthalmic practice.

In reply to a question, Dr. Knapp said it was his practice to use ice-bags to the closed eyelids, but hot water for cleansing mucous membranes.

In closing the discussion Dr. Peck said that by the word *caustic* was implied a destructive agent, and by *astringent* the usual pharmacological acceptance of that class of agents. As the lines of discussion had turned upon the use of cold and hot water in ophthalmic treatment, he offered the statement that the final effect of hot fomentations and ice-cold lotions was the same. He suggested that an application of cold can only be continued as such by a thin layer of muslin or linen, taken from raw ice, transferred to the closed eye, and changed so soon as it acquired a temperature near to that of

the body; a hot fomentation or compress must be of several thicknesses of fabric, as a fresh laundried handkerchief, wrung out of hot water, covered with dry flannel, and renewed so soon as it became reduced to near the animal temperature. The term *cold compress* is an anomaly. He uses cold cloths in this way to combat acute forms of conjunctivitis; he also uses hot water saturated with boracic acid as an irrigant in ophthalmias attended with discharge. It is a well-attested clinical fact that patients like hot applications better than cold.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE MEDICAL COUNCIL'S AUTUMN SESSION—CONJOINT EXAMINATION SCHEMES—THE COLLEGE OF SURGEONS AND THE WILSON BEQUEST—NEW DRAINAGE SCHEME FOR LONDON—THE PUBLISHING SEASON—NEW WORKS AND NEW EDITIONS—THE ENTRIES AT THE MEDICAL SCHOOLS—OVER-PRESSURE IN BOARD SCHOOLS.

LONDON, October 18, 1884.

THE General Medical Council met October 7th. As might have been expected from such an essentially conservative body, Sir Henry Acland has been re-elected President for a third term of five years. I cannot chronicle any important proceedings on the part of the Council. Medical education and examinations were discussed, but it is of little consequence what conclusions the Council arrive at as they have no power to enforce their own recommendations. A considerable amount of time was spent in discussing Sir Henry Pitman's motion, sanctioning the proposed conjoint scheme on the part of the College of Physicians and the College of Surgeons. This has been mooted many times but has never come to anything. The object is to do away with partially qualified practitioners. At present, although the College of Surgeons examine in medicine and obstetrics as well as in surgery, it is only *legally* a qualification to practise surgery. Similarly the license of the Apothecaries' Hall is only *legally* a title to practise medicine and midwifery. There are still a good many men in practice who possess only one of these diplomas.

The license of the College of Physicians is a qualification entitling its possessor to practise all three branches. It is now proposed (not for the first time) that the College of Physicians should relinquish their right to qualify in surgery, and only give diplomas in connection with the College of Surgeons. In the discussion on this subject at the meeting of the Medical Council on the 8th inst., Dr. Quain opposed this scheme strongly, and referring to the Surgical College said: "That amiable fox living in Lincoln's Inn Fields, which never had a tail, went to the College of Physicians and said, How beautiful I am without a tail! do drop your tail and be like me." Sir Henry Pitman's motion was, however, carried, although the weak points in it had been pretty plainly pointed out by Dr. Quain in a lengthy speech. The instituting a complete diploma, qualifying in all branches of practice, and one which is accepted for all Government appointments, is one of the best things the College in Pall Mall ever did for the profession, and it is to be hoped it will think twice before relinquishing its right. It has, too, paid the College pretty well.

The best thing for the College of Surgeons would be to get their diploma recognized as a complete qualification likewise. They ought to be able to do something now, for it is estimated that the Erasmus Wilson bequest will amount to nearly two hundred thousand pounds, instead of one hundred and eighty thousand, as at first expected. One suggestion is that they should endeavor to obtain a charter transforming the college into a university, empowered to grant degrees in medicine and surgery, and located in splendid new buildings erected on one of the sites still vacant on the Thames Embankment.

Speaking of the Thames reminds me of the new drainage scheme of the Metropolitan Board of Works. Your readers will be astonished to learn that, after spending millions of pounds upon the drainage of London, a radical change should be necessary and desirable. What is proposed in the new scheme is virtually to construct an enormous conduit (which would, I suppose, be at least ten miles long) to convey the sewage down to the seacoast in Essex. When it reached the coast it would be necessarily (from the gradients of the conduit) far below sea-level, and to pump it into the sea at ebb-tide machinery would have to be erected still more enormous and costly than that now in use at Crossness and Barking. It goes without saying that this proposal does not receive unqualified or even unanimous approval from sanitary authorities. Economists have protested for years against the fearful waste involved in pouring all the sewage into the river, to say nothing of the pollution of the stream itself. The latter would be removed by the new plan, but the former would still go on. The *crux* is the enormous bulk of sewage with which we have to deal. Still something might be tried. Meanwhile the scheme just described is all that the collective wisdom of the Board of Works has been able to devise. It remains to be seen whether it will be carried into effect.

The approach of winter is, as usual, accompanied by increased activity on the part of medical publishers. Taking students' manuals only, quite a number of new books and new editions are either announced or have recently appeared, and of other works there is quite the usual supply.

A work which will be looked for with considerable interest is a volume of clinical lectures by Mr. Richard Quain, F.R.S., which is announced as being in the press. (This gentleman must not be confounded with his eminent namesake, Dr. Richard Quain, the editor of the "Dictionary of Medicine" which bears his name.) This venerable professor so seldom appears in print and has been so long retired from active practice, that his coming volume will be received with unusual interest.

Mr. Watson Cheyne announces another book on "The Antiseptic Method in Surgery." This (the second work by him on this subject) will doubtless contain some of the results of the researches in the Biological laboratory of the Health Exhibition.

New editions have appeared simultaneously of Erichsen's and Bryant's works on surgery. The former has been considered as the leading text-book for many years past now, although its diffuse and wordy style and its bulk have been great drawbacks to its use by average students. In successive editions it has swelled and swelled until in size it threatens to rival if not outstrip the "System of Surgery," of which a new and (by a rearrangement of type) smaller edition only appeared last year. The latter work, though, is likely to find a formidable rival in "The International Cyclopædia of Surgery."

A fifth edition of Playfair's "Midwifery" is announced. Since its first publication, only eight years ago, it has rapidly become the favorite text-book, to the practical exclusion of all others. Lusk's treatise has displaced it somewhat for the higher examinations, but for all others it is still widely read. A large measure of its popularity is due to the clear and easy style in which it is written. Few text-books for students have very much to boast of in this respect. The best one is, perhaps, the well-known "Manual of Surgery," from the pen of Mr. Timothy Holmes, the editor of the "System." Dr. Robert Barnes is also an able penman, and his work on "Obstetric Medicine and Surgery," written jointly by himself and his son, is certain, when completed, to find a large circle of readers.

Readers of works on medicine are less favored. The two standard books are "Roberts" and "Bristowe," and of both of these new editions have been issued during the

past eighteen months. The former is doubtless a useful compilation for examination purposes, but not an interesting work to read otherwise. Bristowe is perhaps a little more lively writer, but even he makes us long for a return of the literary grace which adorned the pages of Dr. Graves and Sir Thomas Watson. Both of these works, too, sound a very uncertain note in the matter of treatment. Numerous drugs are mentioned under the various diseases, but the directions as to their administration are very vague. We are now promised a new textbook of medicine in the form of a posthumous work by the late Dr. Hilton Fagge. It is to be in two volumes, and from Dr. Fagge's well-known learning and industry is likely to present a faithful reflection of the present state of medical knowledge, and more especially of the teaching at "Guy's."

The number of "full entries" at the medical schools for the winter session is between five and six hundred. By "full entries" is meant the number of students entered for the full course of four years at the hospitals. From this period of time eighteen months is remitted in the case of those who have served a pupilage of that duration with a general practitioner. This applies only to candidates for the ordinary diplomas. The Universities require the whole period of four years to be passed in hospital study, and the College of Surgeons exacts a curriculum of six years for its Fellowship from those who wish to take it from their hospital at once. Graduates in Arts are allowed a year off this.

The discussion on over-pressure in board schools, which was initiated by the publication of Dr. Crichton Browne's report on the subject, is still going on. It appears that after inviting Dr. Browne to inspect and report on certain schools, *accompanied by Mr. Fitch, one of the Government Inspectors*, the Education Department, not finding the report to their taste, first tried to suppress it and then endeavored to upset Dr. Browne's conclusions, and set Mr. Fitch to abuse him. Dr. Crichton Browne has opened fire on his assailants in the columns of *The Times*, and seems to be getting the better of them. The whole subject will probably be well ventilated when Parliament meets. Meanwhile, among the medical profession at any rate, the opinion is pretty general that it has been clearly proved that over-pressure does exist. The rate-payers have long thought so—but for another reason.

THE DANGER OF OPIUM-SMOKING AS A THERAPEUTIC MEASURE.

To the Editor of The Medical Record.

Sir: In the issue of The Medical Record for September 20th, page 317, I notice a short article in reference to "Opium-Smoking as a Therapeutic Measure." Now, while we will all agree with Dr. Thudichum that opium-smoking may prove a palliative and perhaps remedial agent in the cases mentioned, we must, I think, believe that the danger of establishing a habit attending the practice more than counterbalances its usefulness. That the prolonged use of opium in any form is apt to engender the "opium habit," we all know, and I believe that of all the modes of administration tending to such an end, that of opium-smoking is the most potent. This, I think, is exemplified in the graduates of the various opium dens that curse our land to-day. Witness the novice who, feeling a little indisposed, or it may be for the purpose of experiment, repairs to one of these nests of degradation. Now, he does not enter such with the intention of cultivating a habit, and if the possibility of such a danger was suggested to him, he would laugh at the idea. Yet, in nine cases out of ten, when he has finished his first pipe he has forged the first link in the chain that will bind him a slave to this powerful drug. Nor does he stop here; finding the effect so very pleasant, he returns again and again, until the chain is completed and he is bound body and soul to a master that knows no mercy. Now, if there is danger of establishing a habit in the man who, to allay his indisposition or satisfy his curiosity, inhales the fumes of opium, how much more danger is there to him whom suffering induces and his physician advises to resort to it? Why, a hundred times more, I think, and it seems to me that the practice of that man has been limited who can look upon the danger as being comparatively *nil*. Perhaps some may say, "We would not allow our patients to go beyond a certain limit of safety." Ah, but how are you to know just where to place this "limit of safety?" The line of demarcation is certainly not well defined, and when once beyond it all the advice or moral suasion in the world will not induce the poor victim to desist in his degrading habit. Degrading, I say, because, contrary to the opinion of Dr. Thudichum, I believe that the "stories told of the victims of opium-smoking" are not sufficiently colored. They lack the dark and dismal coloring that truly describes the wretched condition to which these poor unfortunates descend. Degrading, because it robs man of all his finer instincts; robs him of his intellect, and makes of him an object of universal commiseration.

I am well aware that there is nothing new or startling in the foregoing, but as the subject is one which cannot be too often referred to, and as many men, especially the younger members of the profession, are prone to act upon every suggestion brought to their notice, I venture to offer it as a protest against the practice of "opium-smoking as a therapeutic measure," and I trust it may not be altogether unheeded.

J. H. Carman, M.D.

South Amboy, N. J., September 23, 1884.

INTRAVESICAL INJECTIONS OF NITRATE OF SILVER.

To the Editor of The Medical Record.

Sir: At the close of an editorial on intravesical injections published in the issue of The Record for September 6th, occurs the following: "Nitrate of silver has been much used in this country and is still used in France; but the less of that material thrown into a bladder, so much the better for the patient."

Now, Mr. Editor, will you favor a large number of practitioners who are constantly using nitrate of silver injections (even the strongest solutions, in cases of cystitis, with the greatest benefit) with substantial reasons for the advice contained in this extract from your article? Many of us, accustomed to this practice, believe the traditional fear of making nitrate of silver injections into the bladder to be wholly imaginary, a veritable *bête noire*, as nothing but good results from their use in our hands in properly selected cases of cystitis, for which troublesome malady they may be safely applied and are often eminently curative after every other measure has signally failed.

The apostle of this practice, Professor Richardson, of New Orleans, one of the most conservative, able, and truthful practitioners in our country, has fully demonstrated in his clinical lectures and private practice, the best results to be derived from the employment of strong intravesical injections of nitrate of silver in cases of cystitis, and his statements are being rapidly endorsed by others in the profession.

In the *Philadelphia Medical News* of November 10, 1883, after a few remarks on the treatment of vesical catarrh, I took occasion to report a most aggravated and instructive case of cystitis treated successfully by the Richardson method, and referred to the favorable experience of others also who had employed it more extensively.

The attention which I then called to the views of Professor Richardson has induced many who, like myself, were no doubt prejudiced against the method, to boldly try it, and subsequent reports, published and by private letters, are most favorable to the practice, and confirm all that has been claimed for it.

For instance, Professor William Gardner, Professor of Gynecology in McGill University, of Montreal, who noticed my communication to the *News*, relates an experience very flattering to the method and recommended it in his lectures to the class. In gynecological cases especially, I venture to predict that there is a great future awaiting a more extended and systematic employment of the stronger nitrate of silver solutions in cases of cystitis. By such means, probably, operative procedures upon the bladder as a *dernier ressort* in rebellious cases of this malady may be obviated.

There are many physicians, in Texas at least, who, relying on the published statements of Professor Richardson, did not hesitate to accept the clinical facts he endeavored to impress, and are now daily employing intravesical injections of nitrate of silver in their practice. We have witnessed no such baneful results as intimated by you. Indeed, our surprise is that the practice is not more generally appreciated.

Professor Richardson's pathological views and rational treatment of cystitis by strong intravesical injections of nitrate of silver were published in the *Medical News and Abstract* for 1879.

It is my opinion that these should be more widely known and acted upon.

Very respectfully,

HENRY K. LEAKE, M.D.

DALLAS, TEXAS.

[We do not see that the success of nitrate of silver injections in properly selected cases of cystitis militates against our view, that the less of it thrown into the bladder the better for the patient; and we were fully aware of the successes and teaching of Professor Richardson when we wrote the article referred to. But there is a wide difference between "properly selected cases" and the indiscriminate use of this solution, which was a matter of every-day practice a few years ago, and is still the routine practice with some physicians.

From our "properly selected cases" we should certainly exclude simple acute cystitis. This point must seem so clear that we will not discuss it. But there are also cases of chronic cystitis which will be less benefited by injections of solutions of nitrate of silver than by other treatment. We do not consider these injections advisable in simple chronic cystitis. In chronic cystitis with vesical catarrh we have obtained excellent results with the nitrate injections; and we have also seen cases, and others are on record, in which the effect of injections of strong solutions of nitrate of silver were so violent as to cause very serious apprehension for the safety of the patient. And in our experience, those cases have done best in which weak solutions were first used, so as to accustom the bladder to the powerful astringent, and then the strength was increased up to the desired point.

There is another objection to the use of very strong solutions in many cases: they may cause such a degree of vesical tenesmus that it is absolutely necessary to administer large doses of morphia to alleviate the pain. In these cases we cannot regard the use of an irritant, at least so powerful as a strong solution of nitrate of silver, as advisable; and much better results are to be expected from iodoform, which, as Mikulicz has pointed out, is especially adapted to mucous surfaces; or from Küstner's method with 1.5000 solutions of corrosive sublimate injected through a funnel-tube. This is especially adapted to the treatment of chronic cystitis in women. We are very much inclined to look upon suppurative cystitis as an affection which should be treated as a suppurating cavity in any other part of the body; but with the disadvantage that we have here a cavity into which there is a constant flow of an irritating fluid—the urine; and that more favorable results would be obtained by cystotomy and thorough drainage; except in women, where the urethra is short and can be so widely dilated as to admit of drainage through it.

We do not, therefore, unconditionally condemn nitrate of silver solutions; we know that they act most excellently in "properly selected cases;" and in the sentence from our editorial, to which our correspondent refers, we did not necessarily intend to convey the idea that the less *quantity* of the silver used the better for the patient, but that the fewer cases in which strong solutions are used the better; the cases being, of course, selected. We cannot, however, agree with our correspondent that there is a great future for the stronger solutions of this salt in gynecological cases, but think that the methods of Küstner, already referred to, of Struppi, or of Fritsch and Jackson more rational, and more peculiarly suited to these cases. We heartily endorse the recommendation of Professor Richardson to inject a solution of common salt into the bladder when the silver solution is too irritating; and will add that we believe the salt solution plays no unimportant part in the result, especially if it be a strong solution. It is not at all improbable that it delays the decomposition of the urine, which is a chief cause of the unhappy results in so many cases.

To conclude, we have seen, as our correspondent says, cases cured by the strong solutions of nitrate of silver when other remedies had failed; and we have also seen a strong infusion of tea succeed when the patient was rapidly going down hill under the use of the silver solution. And when we say that the silver was aggravating the symptoms, we mean that the strong injections were so irritating, and caused such a degree of vesical tenesmus, that it was necessary to narcotize the patient in order to prevent what we believed to be a dangerous degree of shock. If, however, the strong solution does not cause such phenomena, we believe it to be, in properly selected cases, an excellent remedy, and we would not hesitate to use it.—ED.]

FLORIDA AS A HEALTH RESORT.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the April 26th number of THE RECORD appeared an article on the above subject by a Baltimore physician. I eagerly scanned subsequent numbers, expecting some one with facile pen to reply, as the views of the writer were very different from those heretofore published, and from those of physicians in active practice in this State, as well as from facts that can readily be obtained from persons who have been benefited or cured by this climate. For there are men and women in every section of the State—from the Georgia line to the extremity of the peninsula, from the eastern coast that is tempered by "that river of the ocean," the Gulf Stream, to the western shore that is kissed by the waters of the Gulf itself—who bless this "land of fruits and flowers," who speak in glowing terms of the climate that has transformed disease into health, and has changed the hectic flush to the "peach-bloom hue." Is it strange that one who has spent night after night in sleeplessness and pain, racked with cough and annoyed with expectoration, debilitated and enfeebled by months of sickness; and has had all this changed to nightly sleep, as sweet and refreshing as an infant's, the cough allayed, the appetite improved, the health regained—is it strange, I repeat, that such a one should speak in vindication of the sunny clime that has thus benefited him? Can the physician who has seen these changes occur be expected to seal his lips and tacitly admit that the climate of Florida is unsuited to diseases of the respiratory organs? There is scarcely a physician in the State who would not deny such a charge, and *prove* it untrue by patients who are or had been under his care.

In the article referred to, it is admitted that this climate is adapted to cases of rheumatism, chronic neuralgia, syphilis, and gout. We claim that the list of diseases that will be benefited or cured in this climate can be

considerably lengthened. And as physicians we not only claim it, but can prove it by incontestable evidence. A complete list, or a catalogue of the varieties of diseases, will not be attempted, but the kinds of diseases that experience has shown the climate of Florida most adapted for will be given. They are: Tuberculosis in which the deposit is incipient or limited, bronchitis, laryngitis, nasal and pharyngeal catarrh, asthma, nervous complaints, results of overwork, and chronic uterine troubles resulting from congestions. Those aged and invalid persons who, after battling with the storms of life and the rigorous winters of the North, now need warmth and rest and relaxation, enjoy our genial sunshine and rejuvenating atmosphere. There is a peculiar soothing, rest-giving quality of the atmosphere, which especially adapts it to those who are overworked and jaded, or of a nervous character. Before they have been here many days they get the refreshing sleep that has been absent so long. Nowhere in our whole broad land can such a man or woman so quickly get relief as here.

Although the annual rainfall is large (as it should be on this sandy soil), yet the winter months are of the *dry season*. And although we have some rain at this time, there are very few days that the invalid cannot spend a portion of in the open air.

As to humidity, this city will compare favorably with other places. It is less here than at other Florida stations of the Signal Service on the Gulf coast. The courteous and efficient officer at this station, Sergeant Smith, has placed his records at my disposal. (I would state here that he published in the April 4th number of the *Daily Times-Union* of this city an abstract of the meteorological observations at this station, covering a period of twelve years, which would be of interest to many.) I copy sufficient for comparison from the last reports published from all stations:

MONTHLY MEAN HUMIDITY.

	December, 1879.	January, 1880.	February, 1880.	March, 1880.	April, 1880.
Jacksonville, Fla.	77.6	77.1	69.4	63.7	63.0
Los Angeles, Cal.	67.9	65.0	67.0	72.6	77.4
Detroit, Mich. ..	82.1	79.8	75.1	69.6	65.9
New York, N. Y.	73.4	73.3	73.0	70.2	61.0

If space permitted I could introduce reports to show that the changes from warm to cold are not great or frequent. Northers, in the Texas acceptation of the term, do not occur here. Of course, when there is an extremely cold winter in the North, like the last, we have a little colder weather here than the ordinary season. It is about fifteen miles on an air-line to the Atlantic, hence the air is never too highly impregnated with salt or too "bracing." It would be hard to find a more equable and pleasant climate, and at the same time have all the advantages of congenial companionship and the higher civilization. During the fall, winter, and spring months the State is filled with invalids, pleasure-seekers, and those seeking investment, from the more northern, and I might say from every State and Territory, as well as from Europe. It has many advantages and a grand future. Improvement is the watch-word of the day. It is rapidly filling up with the best class of actual settlers. It is too late for derogatory writers to curb her onward march or still her reputation as a health resort.

I intended speaking of the great number of deaths of consumptives that was said to occur at Gainesville. But I have just received the July 19th number of THE RECORD containing an article on that point by Dr. Bradner. My evidence would simply corroborate his.

Yours respectfully,

E. M. NOLAN, M.D.

JACKSONVILLE, FLA., July 24, 1884.

A CASE OF HAY-FEVER IN AN INFANT.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: On the night of September 23, 1884, I was called to attend Mrs. P——, in her confinement. The labor terminated without anything unusual occurring to the mother. At the time she was confined she was suffering from a severe cold. When the child (a male) was born it gave a cry and stopped breathing. As it became purple I cut the cord as quickly as possible, and after rolling it from side to side and using nitrite of amyl it began to breathe with difficulty, as though something was in the windpipe. The eyes were inflamed and were opened only for a moment at a time, and its nose was discharging. The child was plump and well nourished and did not seem to have any difficulty in swallowing. I gave it a drop of whiskey in warm water every ten minutes, which revived it considerably, but it had to be watched and I worked for an hour with it. I gave it minute doses of tartrate of antimony which gave it some relief. Its greatest difficulty was in living between 9 P.M. and 3 A.M.; about 4 A.M. it would begin to breathe easier and would be comparatively easy during the day. I then gave it a prescription containing fluid extract of squills compound, paregoric, and chlorate of potassa, which gave it some relief, but matters continued about the same, being good during the day and nursing well but having the trouble at night. October 7th I gave it the following mixture:

℞. Sodic bromidi..... ʒ j.
Tinct. lobellæ..... gtt. x.
Tinct. opii..... gtt. iv.
Aquæ..... f ʒ ij.
M. Sig.—Teaspoonful at 8 P.M. and repeat in two hours if necessary.

That night it slept without any trouble and has been all right ever since. On the night of the 7th we had a frost and the day was cold. The case is very interesting on account of the age of the patient. The mother was Scotch and the father a Dane. There is no history of asthma or hay-fever in the family. If it was not hay asthma what was it? I do not think the medicine cured the little patient, and the symptoms and termination of the case are very suggestive.

Very truly yours,

S. B. SPERRY, M.D.

DELAFIELD, WIS.

TWO CASES OF TRAUMATIC DIAPHRAGMATIC HERNIA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The cases reported in your issue of October 11th by Drs. Kortright and Harris suggest the publication of the following cases, as they present many points of similarity. They came under my observation while an interne in Bellevue Hospital, and have not been before published.

CASE I.—A stout laborer, aged forty-three, was admitted to Ward 30, April 27, 1881. The history given was that he had been beating carpets upon a roof when a chimney near toppled and fell, burying him beneath the débris. He was thrown forward upon his abdomen, the bricks falling upon his back. He said the fæces "were crushed out of him." When examined at the hospital he was suffering slightly from shock. Simple fractures of the tibia and fibula and of the fourth rib left side were found. There were marks of contusion over the chest and abdomen. Great pain about the sacral region was complained of, making it impossible for him to sit up.

For two days all went well except that the bowels were obstinately constipated. Persistent vomiting then set in, with considerable tympanites, but no pain or abdominal tenderness were found. The pulse became rapid and feeble, although the temperature remained normal. The case was seen by several members of the visiting staff and the diagnosis of rupture of the intestine or a

paralysis from contusion suggested. A displacement of the heart's apex to the right was noticed.

Early May 2d the patient went into collapse and died quite suddenly. The vomiting had continued at intervals but did not become stercoraceous. The bowels remained obstinately constipated. The patient complained at times of dyspnœa. The autopsy was made twenty-four hours after death.

Upon opening the thorax the left chest seemed nearly filled with coils of intestine which extended upward as high as the third rib. The heart's apex was displaced upward and to the median line. The viscera of thorax and abdomen were removed together. A rupture of the left leaflet of the diaphragm was found nearly four inches long, nearer its posterior than its anterior border. Through this opening had passed about four feet of small intestine and several inches of the transverse colon. The intestine showed no evidence of strangulation; it was not even congested, but like the part remaining in the abdomen it was distended with gas. The left lung was compressed into a mass about the size of a fœtal head. The right lung showed slight œdema. The heart was normal. There was no evidence of pericarditis, pleurisy, or peritonitis. No external evidence of injury to liver, spleen, or kidneys. Considerable extravasated blood was found in the substance of the abdominal muscles and beneath them. A separation of the symphysis pubis of one inch was found, also of half an inch at the sacro-ilial articulation. The ligaments at both joints were ruptured but there was no fracture.

In this case the chest was never carefully examined; the pain which was often complained of was referred to the fractured rib. The tympanitic percussion, the displacement of the heart and absence of breathing over the left chest in front, even had they been made out, would have found their most natural explanation in a pneumothorax also caused by the costal injury.

Case II. occurred in the service of the late Dr. James R. Wood. The patient, a man about forty years old, was admitted to the hospital for a compound fracture of the left elbow, produced, it was reported, by a fall of forty feet from a building. The patient was in fair condition, and nothing in his appearance suggested serious internal injuries. On the following day the elbow was exsected by Dr. Wildman, the house surgeon. Very little blood was lost during the operation but the patient never rallied from it. He sank steadily and died in collapse fourteen hours after the operation and forty hours after the injury.

On opening the thorax a large mass was found projecting into it on the left side, which on examination was found made up of the stomach, much distended, the pancreas, the spleen, and about a foot of the transverse colon. These viscera about half filled the chest, crowding the heart to the right and the lung upward and backward. None of the displaced viscera bore evidence of any special violence or of any strangulation. Considerable extravasated blood was found in the substance of the abdominal walls and in the pelvic cavity.

An examination of the diaphragm showed a rupture three inches long in the muscular substance of the left leaflet, extending from the margin of the tendinous portion outward to within an inch of its border.

This specimen is now in the Bellevue Hospital Museum.

L. Emmett Holt, M.D.
23 Park Avenue, New York.

DEATH FROM THE INTRODUCTION OF A STOMACH-TUBE.

To the Editor of The Medical Record.

Sir: An unmarried woman, aged twenty-seven, with a history of chronic gastritis, was being treated by Dr. B——, an itinerant doctor, by introducing a stomach-tube into the stomach and removing the contents—afterward washing out the organ. The operation had been performed twice successfully. At the third attempt he claimed to have passed the tube into the stomach, when she fell back and immediately expired. I was present at the autopsy. The stomach was dilated considerably and in an advanced stage of chronic inflammation. Numerous spots of ecchymosis were present. The heart was pale, and there was fatty infiltration. No other organic changes were noticed. The remainder of the alimentary canal was healthy, as were the liver, spleen, and kidneys. She probably died from paralysis of the heart from the shock of the operation. No coroner's inquest was held. This case may serve as a warning as to what might happen in any trivial operation upon a patient with a weak and fatty heart.

A. D. Bundy, M.D.
St. Ansgar, Ia., September 30, 1884.

THE AVOWED OBJECT OF THE NEW YORK STATE MEDICAL ASSOCIATION.

To the Editor of The Medical Record.

Sir: In your editorial note concerning the New York State Medical Association, you say: "The main object of the Association is to secure to the profession in New York State representation in the American Medical Association." Did not the latter association, at its meeting in Washington last June, throw open its representation to every respectable physician who accepted its code or paid five dollars? It appears to me that if the sum in question will secure personal representation, it is hardly necessary to become a member of the New York State Medical Association for the purpose stated.

You further say: "The question will, therefore, doubtless be raised whether those counties in which medical societies have not changed their old code, and which are still entitled to representation, can send a double set." The true position of these societies is this: The action of the State Society has rendered the old code void in every county society in the State, so far as the power to discipline is concerned. Those societies, therefore, which have not formally adopted the new code are practically without any at all; they are in fact *no-coders*. To this complexion have they come at last.

Junius.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 19 to October 25, 1884.

Alden, Charles H., Major and Surgeon. Relieved from duty at Fort Yates, D. T., and ordered for duty at Fort Snelling, Minn. S. O. 125, Department of Dakota, October 20, 1884.

Vickery, R. S., Major and Surgeon. In addition to his other duties will assume charge of the office of the Medical Director during temporary absence of Major J. C. McKee, Surgeon U. S. A., Medical Director of the Department. G. O. 34, Headquarters Department of California, October 8, 1884.

Winne, C. K., Captain and Assistant Surgeon. In addition to his duties as Post Surgeon at Benicia Barracks, will also attend the sick at Benicia Arsenal, Cal. S. O. 122, Headquarters Dep't of Cal., Oct. 13, 1884.

Strong, Norton, First Lieutenant and Assistant Surgeon. Assigned to duty at Fort Union, N. M. S. O. 198, Department of Missouri, October 4, 1884.

Phillips, John L., First Lieutenant and Assistant Surgeon. Transferred from Department of the East to Department of Dakota. S. O. 245, A. G. O., October 18, 1884.

Official List of Changes in the Medical Corps of the U. S. Navy, during the week ending October 25, 1884.

Bloodgood, Delavan. Promoted to the grade of Medical Director, August 22, 1884.

Oberly, Aaron S. Promoted to the grade of Medical Inspector, March 28, 1884.

Wells, Henry M. Promoted to the grade of Medical Inspector, August 22, 1884.

CIRRHOSIS OF THE PANCREAS.

By CHARLES WARRINGTON EARLE, M.D.,

PROFESSOR OF OBSTETRICS, COLLEGE OF PHYSICIANS AND SURGEONS; AND OF DISEASES OF CHILDREN, WOMAN'S MEDICAL COLLEGE, CHICAGO, ILL.

THE occurrence of four cases of chronic inflammation of the pancreas in private practice, within the space of three years, has led me to review the literature on the subject with more than ordinary care.

That diseases of this organ are rare is undoubtedly true; but it is also a fact that comparatively little attention, up to this time, has been given to their investigation and study.

Bartholow says that so little is definitely known of diseases of the pancreas, that many systematic works omit the subject entirely. Atkin, in his large work, does not speak of disease of this organ. Hartshorn, editing Watson, devotes about fifteen lines to the consideration of this subject. Flint and Wood have only short articles, and Da Costa has collected the history of but forty-five cases, upon which he bases the brief remarks made in his work on diagnosis. One may look through scores of journals without finding an allusion to diseases of the pancreas.

For anything like a comprehensive article, we are obliged to go to Ziemssen, and here we are met by the statement that the great rarity of these diseases has hindered the more rapid development of our knowledge of the bearings and pathological changes in the organ.

It will go without saying that in the living or dead we neglect to examine this organ as we should; and for obvious reasons, however rare or frequent diseases of the pancreas may be, their diagnosis will remain obscure, and in the hurry of the post-mortem, often necessary, the gross appearance of the abdominal salivary gland will not be considered, and in many cases the organ will not be found.

CASE I.—Edward E——, aged sixty-five, American, contractor and builder. Was seen first November, 1880. Previous to this sickness he had never needed the service of a physician, and had always led a very active life. During the early part of the year he commenced to emaciate, and applying to a neighboring physician was given some medicine for malaria. He was not relieved, but was able to transact business. Throughout the summer months his appetite had changed greatly, and he had no desire for meats, but relished milk, mush, etc.

At my first visit I noticed his white anæmic appearance, and obtained the following personal history: His ancestry were long lived, and he had never had syphilis. There was nothing abnormal as regards his nervous system. His mental faculties were all good, and he only complained of a roaring in his head and ears. His lungs were without a trace of disease, but he was short of breath on account of weakness. The heart performed its functions perfectly, but there was heard a slight anæmic murmur. There was nothing abnormal in any of the abdominal organs, as far as I was able to examine them, and neither albumen nor sugar was found in his urine. His passages from the bowels were black and thin, with occasionally little lumps of blood and mucus. His pulse was 100; temperature, normal. The tongue perfectly clean, but, with mucous surfaces and integument, was almost white; indeed, this was his most striking symptom. He looked jaundiced, but a close examination showed it to be a whiteness of the tissues. The only painful spot on his entire body was at the epigastrium, and that was not severe and only produced by pressure. He complained of thirst and was occasionally nauseated.

I was unable to diagnosticate the case, but believed that he was suffering from some disease of nutrition; exactly the organ affected I was not able to determine.

I treated him for a few days with tonics, mineral acids, strychnia, and a generous diet. There was no improvement, however, and Dr. N. S. Davis saw him with me in consultation.

We did not attempt to name the disease, but concluded that somewhere in the line of lymphatics or in some part of the digestive apparatus, there was a very serious disorder, which in all probability would cause his death. He died one month after I made my first visit, having, however, passed into the hands of another professional gentleman.

In company with this gentleman I made the post-mortem. There was nothing unusual to be seen in any of the principal organs of his body, excepting the very marked whiteness of all the tissues, and not until I had removed nearly the entire viscera of the abdomen and came down upon a white indurated pancreas did I find the seat of disease.

The gross and microscopical appearance of this organ are given by Dr. S. J. Holmes, Lecturer on Pathological Histology at Rush Medical College: "Pancreas contracted; consistency abnormal; fibrous to the touch; color white. Under the microscope the connective tissue is extensively augmented, and there is obliteration of certain glandular vesicles, and atrophy of others, induced by the pressure of the new-formed connective tissue as it contracted in its maturity. There was slight fatty degeneration of the parenchyma of the kidney."

CASE II.—Mr. S. K. R——, aged fifty-seven, American. This gentleman, who had been connected with the printing and publishing establishments of this city for years, was first seen, professionally, January, 1882.

He was known among his associates as a most powerful and healthy man, though two years ago he commenced to fail in strength—yet up to within two months of his death he continued to transact business.

I learned at my first visit that about twelve years ago he had an extensive eczema, and has always been a dyspeptic. He has also been troubled with hemorrhoids, and even now every passage is attended with very great pain and some blood escapes. He has lost about sixty pounds. The color of his skin is very white, almost yellow, and yet the conjunctiva is perfectly white.

His pulse, respiration, and temperature are perfectly natural. He complains principally of pain in the rectum, and a slight sickness at his stomach when food is taken. He has also a feeling of weariness, and a consciousness that he is continually losing flesh. He does not like meat of any kind, or eggs.

He has been under the care of several physicians, who, in the main, have promised a cure. It was diagnosticated by one as a "severe physical and nervous prostration."

During the first months I treated him with pancreatine, pepsin, and the mineral acids, and at a visit made February 6th he claims that he has gained three pounds. He is having, however, alternate diarrhœa and constipa-

tion. His color is no better, but he does not complain of quite as much pain on the passage of his bowels. During all this time his pulse and temperature is natural. The pulse, if anything, is a trifle slow and without volume.

About this time, in a conversation with him, he asked me the direct question, and pressed me for an answer, as to whether I could assure him of a cure. After considerable hesitancy, and only after repeated solicitations upon his part, I told him that I was very much afraid that he had some disease that would ultimately cause his death. That was the last time I prescribed for him.

June 26th I made him an unprofessional visit. He was now being treated by rubbing, and was assured that in the course of a few days he would be greatly improved. His pulse was 78, temperature only 97½°, appetite poor. His bowel difficulty was entirely removed, and the pain which he formerly experienced had ceased. He ascribes the cure of this particular symptom to a root syrup with molasses injections. All the pain and soreness which he now feels is just below the ensiform cartilage.

He is expectorating a large amount of mucus, and has at various times vomited something which his attendants described as looking like fat. About two weeks previous to this visit he vomited a large amount of coagulated blood, the hemorrhage continuing for some eight hours, and the quantity escaping was estimated to have been about two pints; of course, it was mixed with saliva and other secretions.

At this visit it appeared to me that he was certainly failing, and that a mortal result was liable to take place at any time. He was still hopeful, however, and was encouraged by his attendants. He died June 30th.

In the presence of Drs. R. N. Foster, Cashman, Mr. J. D. Waller, and the writer, Drs. Graham and Haven made the autopsy. In compliance with the wishes of the friends, the abdomen only was opened. There was considerable fat between the integument and the abdominal muscles, but nothing abnormal as regards the position of any of the viscera.

The whiteness of the tissues, so marked at the autopsy of Mr. E——, was also present in this case. With this exception nothing pathological was found until the pancreas was reached. This organ was hard and slightly enlarged, and filled with spots plainly seen with the eye. The bowel was perhaps contracted in its calibre in some places, but in the rectum, where so much pain was experienced up to a short time before his death, there was absolutely no trace of disease.

There was no abrasion in the continuity of the mucous membrane of the stomach, and the hæmatemesis, which was so profuse a few days before his death, was probably caused by pressure of the enlarged head of the pancreas on some blood-vessel, or it may have been from minute capillaries in the mucous membrane of the stomach which could not be discovered with the eye. The microscopical examination was made by Professor Marie J. Mergler, and resulted as follows: "The pancreas measured nine inches in length, two and one-half in breadth at the head, two at the tail, and was one inch in thickness. The whole organ was denser than normal, and its surface presented numerous yellowish-white spots from one-fourth to one-half inch in diameter. These light portions were considerably denser than the rest of the organ. On microscopic examination there was found increased amount of connective tissue throughout the organ, especially in the light-colored portions."

Case III.—Mrs. R——, aged 36, American; housewife. Suffered with most terrible nausea and vomiting during the first three months of pregnancy. Seen in consultation with Dr. Haven. Died from exhaustion. Microscopical changes furnished by Professor Mergler, and correspond in every particular with the others.

Case IV.—Mrs. G. R——, aged 25, American; housewife. Passed through her first pregnancy and was safely delivered. Made a good recovery. Six weeks after commenced to cough, which persisted three or four weeks. Then a diarrhœa with great emaciation troubled her four months. During this time emaciation and whiteness of tissues were the most prominent symptoms. Died of exhaustion. The pancreas was hardened, connective tissue increased, glandular tissue obliterated.

Physiology.—In considering the diseases of an organ, the function of which we at best are not particularly well informed of, it may be well for us to study its physiology. That the pancreas is a racemose gland, and lies crosswise behind the stomach and the left lobe of the liver, and is supplied with blood-vessels and excretory ducts, is well known. Some questions are pending as regards its minute structure, but, on the whole, it is not unlike the other salivary glands. It is fairly settled now that it has a most important part to perform in the digestion of not only fats, but all kinds of food. It acts upon starch, upon albuminoid materials, and also upon the fats. Its power of converting starch into sugar is greater than that of the other salivary glands, and about all that may be said concerning the saliva may be repeated in regard to the product of this gland. Its power of digesting albuminoid compounds, as well as emulsifying neutral fats, has been fully demonstrated by a large number of physiologists. While the bile possesses nearly the same power, in all probability the complete digestion of fat is only perfected by the combination of the juices of these two organs, the liver and the pancreas.

Pathology of the pancreas.—"On account of the slight pathological importance of the pancreas, only the most important changes which occur in the glandular tissue or the ducts will be considered."[1] And yet four cases have died in my practice in four years from inflammation of this organ. The above quotation simply illustrates what I have already remarked, that the pancreas has not been studied as other less important organs have.

In addition to what I shall have to say in regard to the pathological appearances found in my cases, I desire to recapitulate what Rokitansky presents in regard to the abnormities and pathological conditions of the pancreas. In the first place, it may be absent; sometimes only partially developed, and the thyroid and thymus glands, with the pancreas, have been found in one mass; the gland may be enlarged simply from ordinary induration. It is diminished in size sometimes in persons of an advanced age, and sometimes, too, from chronic inflammation and adipose infiltration. There may be induration with enlargement, or extreme softening with relaxation and succulence of the tissue. Inflammations of this organ are either acute or chronic, and are either primary or secondary. When secondary, usually it is metastatic. In the acute forms of inflammation the gland is found reddened, congested, and relaxed; there is acute infiltration of the interstitial and cellular tissue. In the chronic inflammation there is hardening of the cellular tissue and obliteration of the glandular structure with sometimes permanent enlargement, followed occasionally with atrophy of the glands. New growths are not particularly frequent. Tubercle has never been discovered in the pancreas, and cancer rarely attacks the gland primarily. The pancreas may be the seat of an extensive accumulation of fat. Indeed, the whole organ may be converted into one mass of fatty tissue. Cysts, cartilaginous and osseous growths are found very rarely. Cancer when found involving the pancreas is usually a complication of extensive carcinomatous diseases of other organs. The ducts of the pancreas may be dilated, or compressed, or completely obliterated

Calcareous deposits in the excretory ducts, giving rise to obstruction or obliteration, may be found, or there may be an accumulation of secretion and consequent dilatation.

Orth differs in some respects in regard to the frequency of tubercle and primary cancer, but in the main agrees with the compilation given above. Ziegler presents

[1] Orth: Diagnosis of Pathological Anatomy, p. 333.

nothing of importance in his recent work on pathological anatomy.

Having now considered the physiology and pathology of the organ we are in a position to study the general symptoms of diseases of the pancreas.

The first symptom which I will notice is emaciation, proceeding to an unusual degree, and where it cannot be explained in the usual manner. We ought not to forget, however, that great loss of flesh is liable to take place in diseases of any of the digestive apparatus, and it will be only by excluding other diseases, and by carefully watching the case, that we shall be able to gain any information from this source. It is altogether probable that the function of the pancreas may be taken up and very largely compensated by the other digestive fluids, and we do not forget that experiments have been made upon the lower animals, and young dogs have recovered and lived after extirpation of this organ ; but this symptom (emaciation) associated with tenderness in the vicinity of the pancreas, and with no apparent disease of other neighboring organs, should be taken, it appears to me, as a possible indication of disease.

A second symptom, and one which, it will be remembered, was present in one of my patients, is a flow of saliva-looking fluid from the mouth. This occurred to a very considerable degree in the case of Mr. R——.

We are well aware that in diseases of the stomach the eructation or spitting of saliva-looking fluid is a very prominent symptom, and unless we take into consideration other symptoms, referable to the pancreas, this one symptom, it appears to me, loses its diagnostic value.

The presence of fat in the stools is another symptom. While the passage of fat in stools has been regarded as a symptom of very great value, it should be remembered that when a large amount of fat is taken with the food, the ordinary secretions of the digestive apparatus do not appear to be able to digest this unusual amount, and a fatty stool in such a case would be of no diagnostic value.

It appears to me that in the matter of fatty dejections it could be regarded as a diagnostic symptom only where we could demonstrate that a too great amount of fat was being taken, and that the other organs having to do with the digestion of fat were in a comparatively healthy condition.

One of my patients vomited a large amount of fatty material. I do not now remember of seeing this recorded as taking place in any other case of disease of the pancreas.

Among other symptoms, we should speak of pain and tenderness in the epigastrium; but we should also remember that a very great variety of diseases of the abdominal organs in this vicinity, such as diseases of the stomach, liver, lymphatics, aorta, spine, etc., are attended with pain and tenderness.

In the consideration of individual symptoms, which will receive attention at another place in this paper, I shall hardly mention the possible connection of pancreas disease with diabetes mellitus. This complication does occur in some cases, but the explanation of the last-named disease, as we now understand it, would demand a discussion relating to certain parts of the nervous system at greater length than the limits of this paper would permit. Sugar was not present in any of my cases.

Etiology.—Concerning the cause of pancreas disease, whether it be anæmia or hyperæmia, atrophy or hypertrophy, acute or chronic pancreatitis, nothing is definitely known.

It seems, however, that constitutional syphilis and alcoholic excesses have much to do with producing these diseases, and from Cases III. and IV. in my enumeration it would seem that pregnancy may be an exciting cause. Other causes have been assigned, but they are mostly problematical.

Trousseau says that the pancreas undergoes the same changes that the liver does in chronic alcoholism, and that the pancreas has six times been seen by the same observer to be affected; sometimes altered in the same manner as the salivary glands, which are described as soft, yellowish, and having their epithelium manifestly invaded by granulo-adipose degeneration, or shrivelled or atrophied like the liver of cirrhosis. I have recently had the opportunity of making an autopsy in a case where the immediate cause of death was dilatation of the aorta with valvular disease, but in a person who had a syphilitic history; indeed, in 1872 and 1873 he was under my immediate care. Among the organs involved which we found at the post-mortem, in addition to those having to do with the immediate cause of death, was hyperplasia and enlargement of the spleen, fatty infiltration of the liver, and marked evidence of *chronic interstitial pancreatitis*. I mention this case not because it has any particular connection with pancreas diseases, but as a case where syphilis was known to have existed, and where there was found, ten years after, evidence of chronic inflammation of the pancreas.

I desire now to pass in review the four or five principal symptoms which have been supposed to be always present in disease of the pancreas, and to examine into other diseases where we frequently find these same symptoms, in order to arrive at some definite conclusion as to the worth of the so-called pathognomonic indications. Such symptoms as emaciation, the presence of fatty stools, the profuse flow of saliva, etc., what are they worth to us in diagnosticating a case of pancreatic disease?

It must be remembered, at first, that in all diseases of the digestive apparatus which continue for any length of time there is more or less emaciation. We find it, too, in diseases of the stomach, and in chronic diseases of the intestinal canal. Particularly do we find emaciation in cancerous diseases of the bowels, where, in addition to marked cachexia in almost all cases, we find the loss of flesh is very great; there are, however, exceptions to this, and persons have been known to suffer from cancerous diseases of the intestines, verified by an autopsy, and yet lose but very little flesh. Extreme emaciation of the body usually takes place in stenosis of the bowels, whether it be from cancerous disease or other causes.

In the intestinal parasitic disease called anchylostomum duodenale, a malady which we know but little of in this country, emaciation is spoken of as one of the prominent symptoms. This is a disease where the parasite lives on the blood which it takes from the tissues, and not only does it abstract what it needs for its own sustenance, but as it changes its position it leaves wounds from which there is a constant escape of blood.

We have, then, here a disease with all the symptoms of chlorosis, with its attendant paleness of the general integument and of the mucous membranes, with great fatigue, dyspepsia, and palpitation of the heart, which will require great care to differentiate from other diseases of bad nutrition. The parasite gradually extracts blood from the mucous membrane of the alimentary canal, and in this way produces not only all the symptoms of anæmia, but the particular symptoms of emaciation of which I am now speaking. The fact, however, that this disease takes place in, or is imported from, tropical climates, will enable us to exclude it when we are trying to differentiate pancreas diseases.

Emaciation is also a symptom of a dilated stomach, a disease, by the way, which it appears to me takes place with greater frequency than, perhaps, the profession recognizes. In this difficulty, while the stomach is very large, with apparent obesity, yet there are all the symptoms of poor nutrition. The patient is pale, hollow-eyed, and is reduced nearly to a skeleton. There is also with this a real loss of physical strength.

We find emaciation, too, in cirrhosis of the liver attended with anæmia and loss of strength. This symptom in cirrhosis appears frequently early, and long before those more prominent symptoms, such as ascites, etc., which occur toward the end of the disease. In some

cases it is only when nutrition has become disordered and emaciation and loss of strength are noticed that the patient first realizes that he has some disease.

We find emaciation in splenic diseases with rigors and a fever, ofttimes of a hectic character, with sweats, œdema, slight jaundice and diarrhœa, the patients in the meantime emaciating rapidly.

This is a symptom, too, that we find present in certain nervous diseases, and along with the other symptoms of a unilateral progressive atrophy of the face we find emaciation taking place as a symptom. In Basedow's disease it is a very prominent symptom. In a paper which I presented to the Illinois State Society some years ago, I considered at length the symptom and progress of this disease, and placed on record the history of a case where the emaciation had taken place to such a degree that a lady weighing ordinarily one hundred and seventy pounds became reduced to probably ninety. In such a case, however, there are so many other symptoms present that we can at once exclude any probability of pancreas disease.

Emaciation is present in scrofulous and tubercular diseases, and proceeds to a very considerable extent with the fever and loss of appetite which we find in chronic pleurisy or empyema.

It is thus seen that if we place great stress upon the one symptom of emaciation to help us in making up our diagnosis in pancreas diseases we shall become involved in great perplexity, for we have already seen that many diseases, and many of them quite as obscure as those of the pancreas, are attended with constant and progressive loss of flesh.

In regard to the second symptom—that of the flow of saliva, or a mucous-colored fluid from the mouth—we find that this, too, is present in a considerable number of diseases, although not to the same extent that we find emaciation.

The attempt that has been made to base a theory that a sympathetic or vicarious relationship exists between the pancreas and salivary glands has no good foundation, and the increased secretion of saliva which is present in a very considerable number of chronic diseases of the stomach has no connection whatever with any function of the pancreas, and in those cases where a considerable amount of saliva is vomited in the morning, in all probability it has been secreted and swallowed during the night.

It has appeared to me, however, since I have watched Cases III. and IV. of cirrhosis of the pancreas in my practice, that there may be some reasons for expecting that the great abdominal salivary gland (the pancreas) may be influenced by the same causes which produce impressions on the salivary glands in the mouth. The demonstration of this must remain for future study.

In diseases of the nervous system we find an increased flow of saliva, but we are usually able to find some local paralysis as the direct cause. In progressive bulbar paralysis there is sometimes a constant flow of saliva from the mouth, sometimes watery and sometimes more like transparent mucus, and yet progressing to such an extent as to be of great annoyance to the patient. It is frequently present in facial paralysis and in some forms of neuralgia.

Coming to consider the presence of fat in the stools and other excretory products it seems that we really have in this a symptom of more importance than any hitherto mentioned, but it is not always pathological, as it has been observed in the fæces of healthy persons who are partaking of a greater amount of fat in food than was usual, and more than can be digested by the apparatus having this to accomplish.

It is also found in the stools of children apparently healthy, and in some cases the white lumps which we suppose to be undigested casein are largely made up of fats; the fatty acids combine with lime in forming them.[1]

It has been seen in the stools of patients suffering from slight jaundice and other evidences of a temporary disease of the liver. There is probably associated with this, at least in some cases, a partial occlusion of the pancreatic ducts, and recovery will usually take place.

Fat is found sometimes in the stools of persons afflicted with chronic jaundice, where there is occlusion of the ductus choledochus, either alone or associated with temporary closure of the pancreatic duct. If a large amount of fat made its appearance it would be an indication that the fat digestive functions of both organs, liver and pancreas, were probably impaired.

Fatty urine has been found either alone or in the same patient where fatty stools have taken place. Several cases of this kind are on record, and among the post-mortem revelations some disease of the pancreas has been found.

In looking over the literature for cases in which fat has been found in the urine, I was impressed with the similarity of the symptoms present in pancreas disease with fatty urine, and the history of cases described under the head of *chylous urine*.

In 1876 Professor Hollister read a paper on the subject of chylous urine before the Illinois State Society, and I cannot but notice the analogous symptoms as related in his paper.

The emaciation, epigastric pain, and loss of fat correspond to a very considerable degree with those same symptoms so frequently present in diseases of the pancreas. The theory was even then advanced as to the possibility of some undiscovered connection between the lacteal or lymphatic system and the urinary passages. More recently the thought has been advanced as to the passage of large amounts of fat from adipose tissue of the body to the blood, and thence through the vessels of the intestinal mucous membrane being set free. The discovery of the embryo of a round worm in the blood of those affected with chyluria has happily made its pathology certain. I wish I might say as much in regard to diseases of the pancreas.

The vomiting of fat is a symptom which I do not now remember to have seen mentioned in any article on diseases of the pancreas to which I have had access. It was present in the case of Mr. R——, and considering the fact that the head of the pancreas was considerably enlarged, so much so as in all probability to press against the duodenum, it is not surprising that a regurgitation took place.

If blood or bile may be diverted from the intestinal canal and thrown back into the stomach when pressed upon by a cancerous or any other indurated mass, it seems possible to me that the fatty food which has been partially acted upon by the secretions of the duodenum in the vicinity of the pancreatic and biliary ducts may be pressed back into the stomach and vomited as fatty matter.

In conclusion, I can only say that notwithstanding the fact that I have seen four cases of cirrhosis of the pancreas, and have studied faithfully all the literature at my command, diseases of that organ will still remain to me difficult to diagnosticate.

In my second case, more from the striking similarity in the general appearance of the two men than from any one particular symptom, did I venture to suggest pancreas disease. More by excluding everything else, it appears to me, must we base our diagnosis.

In my third case, Dr. Haven is kind enough to give me credit for speaking of disease of the pancreas as the possible cause of such a degree of emaciation; and in my fourth case the diagnosis was made and adhered to, the autopsy justifying the opinion.

It is not clear that fatty matter was passed from the bowel in either of my cases; but it was evident in both that the fats were not relished, were not well assimilated if taken, and that the system was destitute of those fatty constituents upon which blood and tissue must be replenished.

[1] Professor T. Uffelmann: Arch. Kinderheilkunde, 1880.

Notwithstanding the fact that fat was not passed in my cases, after excluding those cases where fat is normal or accidental, I should certainly regard the presence of fat in the stools as one of the most valuable symptoms in making our diagnosis.

The value of vomiting fat as a sign of pancreas disease must be studied in a greater number of cases. I simply place on record the fact that it was present in my second case.

Emaciation takes place in so many diseases that unless we find the majority of the other symptoms of pancreas disease present, it cannot be taken as a sign of great importance.

The extreme whiteness of the tissues will be regarded the most prominent symptom.

Treatment.—I have nothing to add which is new; but with the improvement which took place in the case in which I gave the pancreatine but a very imperfect trial, I certainly feel that the use of this remedy should be insisted upon until its value is fully demonstrated—either pancreatine as we have it in the shops, or in emulsion, or what would probably be better than either, the freshly prepared calves' or pigs' pancreas.

These preparations should be given some time after each meal, and without acids.

These remedies in the marasmus and infantile dyspepsias, where there exists an inability to digest fatty and starchy foods, should, it appears to me, have a more extended trial than we have hitherto given them.

Conclusions.—First, from the study of diseases of the pancreas which I have given up to this time, it appears to me that inflammations of this organ are more frequent than we have hitherto supposed.

Secondly, chronic inflammation of this gland is characterized by great loss of flesh, extreme whiteness of the tissues, and generally pain in the region of the affected organ. The appetite in some cases continues excellent, and the patient may take food until the hour of death. The pulse and temperature remain nearly normal. Among other symptoms which may or may not be present, is the passage of fat from the bowel or its eructation from the stomach.

Thirdly, the pathological processes produce the organ hardened, connective tissue increased, glandular and secreting structure pressed upon or obliterated.

Queries.—1. Are not a considerable number of cases commonly diagnosticated as pernicious anæmia, leucocythæmia, chlorosis, etc., due to chronic inflammation of the pancreas?

2. Have we here a disease to which the name "pancreatic anæmia" should be given?

Idiopathic Convulsions of the Tongue.—Dr. O. Berger relates, in the *Neurologisches Centralblatt*, the case of a woman, twenty-eight years of age, who was seized suddenly, without any prodromata, and in the midst of perfect health, with a peculiar spasm of the tongue. She experienced a sensation of tension in the supralaryngeal region immediately beneath the chin, and then the tongue, which seemed to the patient to be enormously swollen, underwent a number of undulatory movements. At the end of about ninety seconds the organ was projected violently forward, striking the dental arch with a perceptible noise or appearing between the lips. These convulsions occurred rhythmically, succeeding each other fifty or sixty times a minute. Speech and deglutition were impossible during the continuance of the attack, which, however, caused no other trouble. The author cites another case of a man, forty-two years of age, who had similar convulsions, not preceded, however, by the undulatory aura. This patient frequently wounded his tongue by closing involuntarily his teeth upon it. Dr. Berger referred these spasms to central excitation, cortical or bulbar, of the hypoglossus. A cure was obtained by galvanism and hypodermic injections of atropine.

YELLOW FEVER AT PANAMA—ITS CAUSE AND TREATMENT.

By C. H. WILLIAMSON, M.D.,

U. S. STEAMER ACAPULCO.

Having had some experience with yellow fever at different times, and most recently on the Isthmus of Panama, I am induced to give a few impressions formed in regard to the cause and treatment of that disease, though the views presented may prove neither novel nor interesting to the profession.

Yellow fever is unquestionably a disease of *marine* origin, and an essential element in its production is *salt-water*, with the organic vegetable and animal matter contained therein. This is established by the fact that the disease is never known to originate away from the sea-coast or where salt-water does not permeate. Ordinary malarial fevers may arise in any locality where heat, moisture, vegetation, and telluric influences combine to produce them, but the specific fever under consideration never can be produced without the additional element derived from the sea or its tributaries. Whether this is evolved from the decomposition of the vegetable or animal constituents of the salt-water is uncertain, but it is probable that *both* contribute a share. Dr. Domingo Freire, of Rio de Janeiro, who claims to have discovered the germ of the fever in the "cryptococcus exogenicus," says it is of *vegetable* origin, but does not, I believe, ascribe it necessarily to a marine source. I am inclined to the opinion that the *animal* matter of the infusoria in sea water, by its decomposition, plays a more important part in the causation of the disease than the *vegetable*. This is shown by the prevalence of the fever on board vessels into whose holds sea water has leaked and saturated the timbers, and it is probable that this water in its percolation has borne with it more of its animal than vegetable constituents, whose decomposition in the hot and unventilated apartments, combined with other favoring, deleterious agents, infects the atmosphere and generates or maintains the disease. This is chiefly the case with wooden vessels, as those built of iron rarely leak, have no timbers to saturate, and can be kept dry and clean; hence are always more healthy.

Another reason for the belief in the marine *animal* origin of the fever is, that in all tropical regions where it chiefly prevails *coral reefs* abound, and animal marine life is most abundant. These reefs, when left bare by the tides and exposed to the intense rays of a tropical sun, afford abundant material for rapid decomposition, and are doubtless most active agents in polluting the air.

The town of Aspinwall, on the Isthmus of Panama, is located on a small island almost surrounded by a coral reef. Here yellow fever is endemic, and sporadic cases occur at all seasons; but occasionally it becomes epidemic, as was notably the case in the spring and summer of 1880. At that time there was an unusual prevalence of low tides and the reef was exposed nearly all the time to the sun, emitting an extremely disagreeable odor, and cases of yellow fever were more numerous in the residences near and fronting the beach than in other localities, though they occurred in other parts of the town, where coral rock, broken from the reef, was taken to fill up low places and prepare for the foundations of buildings. A stop was soon put to this operation, but of late it has been renewed, and cases of yellow fever continue to occur. Two vessels that took coral rock as ballast had this fever break out on their voyages. If the germ of this disease is evolved, as I think it is, from the polyps of coral and other decomposing marine animal matter, it finds a most congenial atmosphere in which to develop and spread (and it only can do so where the conditions are favorable) at Aspinwall, where heat, moisture, and filth of every kind render it one of the most abominable places on the globe, and where the utter neglect of all sanitary measures causes wonder that human life can exist at all.

The germ of the fever, whatever it may be, is readily conveyed by fomites in the air from an infected place, and will rapidly show its effects wherever carried, if heat and all other concomitants are supplied, but in a temperature below 70° it cannot survive, and at once disappears.

That the disease cannot be conveyed by *personal* contagion is too well established a fact to admit of doubt, and was fully proved in the terrible epidemic that prevailed at Norfolk, Va., in 1855.

In regard to the treatment of the fever, as the kidneys play the most important part in its pathology, special attention should be paid to their function and every effort made to keep up their secretion as indispensably necessary to a cure. Suppression of urine is the worst symptom, and, however grave all the others may be, if that one is absent, there is hope of recovery. I have seen patients get well after having "black vomit," and all the other most unfavorable symptoms *except suppression*, and until that sets in the prognosis is favorable; but after it appears and continues for over twenty-four or thirty hours the case may be regarded as hopeless. In those attacks where from the onset the brain bears the onus of the disease and maniacal delirium appears early, soon subsiding into profound coma, death generally speedily ensues; but with the exception of these brain and kidney complications, and their proportion is not very large, the fever usually yields to prompt and proper treatment. This should be commenced at once with hot mustard baths of the lower extremities, and the administration of a brisk cathartic; the patient then put to bed and covered with blankets; given drinks to promote diaphoresis, and sinapisms applied over the epigastrium and region of the kidneys. If after free perspiration and purgation the fever does not subside, a tentative dose of fifteen or twenty grains of quinine may be given, but should not be repeated if it fail to reduce the temperature or increases the headache. Should it act otherwise it may serve to abort the disease, and can be repeated in a smaller dose in three or four hours. The fever persisting, the use of diuretics and refrigerant diaphoretics should be vigorously employed, particularly the former, to promote the urinary secretion. A combination of potass. nitrat., grs. x.; spts. nit. dulc., ʒ j.; tinct. aconit. rad., gtt. j.; aquæ, ℥ ss., every second hour, I have used with advantage, and found it generally retained by the stomach. The acetate or chlorate of potass. may be substituted for the nitrate in this prescription; or the *latter* may be given with sulphur. sublim. and pulv. carbonis (one as a germicide, the other as an antiseptic), with good effect. The action of the kidneys may also be promoted by the bitart. potass. as a drink, and the application of dry cups, turpentine stupes, and fomentations to the loins. When gastric irritability sets in, the stomach should be kept as quiet as possible and nothing given as long as it is quiet; but if it will not remain so, of all the remedies I have found nothing better than milk and lime-water to allay the nausea and vomiting. When "black vomit" occurs I have arrested it with ergot and tinct. ferri chld.

Having thus outlined the general system of treatment I have found most beneficial, regard for your valuable space warns me not to go more into detail of the variety of remedies employed to meet the different indications in the stages of remission and collapse.

The temperature of the apartment of the patient should be kept as uniform as possible, and during the entire period of the attack he should be kept moderately covered by bed-clothing and never subjected to a sudden change. His diet should consist of milk, gruel, and animal broths, given in very small quantities at a time and frequently repeated, and stimulants employed when indicated after the subsidence of fever. A return to solid food during convalescence should be very gradual, and great caution in this matter is imperatively demanded.

THE COCA LEAF AND ITS ALKALOID.

By WILLIAM OLIVER MOORE, M.D.,

PROFESSOR OF EYE AND EAR DISEASES, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

The importance which has been attached to the alkaloid of the coca leaf during the past few days in ophthalmic surgery has led me to bring together a few facts, historic and otherwise, for the general reader, knowing that doubtless they would prove of interest.

Cuca, or coca (erythroxylon coca), as called by the natives (erythroxylum peruvianum), is found wild in the mountains of Peru and Bolivia, and is also cultivated on high altitudes. The leaf is the part of the plant in which the active principle resides. These leaves, which resemble those of the tea-plant, are gathered from plants varying in age from one to upward of forty years. They are considered ready for plucking when they break on being bent, and are gathered in March (after the rainy season, this being the most abundant crop), in July, and in November. Good samples of the dried leaves are uncurled, with a deep green upper and a gray-green lower surface,and have a strong, tea-like odor. Bad specimens have a brown color and a smell resembling camphor The flowers of the plant are small and white, and are succeeded by red berries.

The seeds are sown in December and January; the cultivation of the plant gives employment to thousands of the people, and the annual production in Bolivia and Peru in 1864 was estimated at two million five hundred thousand dollars in value.

The green leaves are spread on coarse woollen cloths and dried in the sun, then packed in bags, which, in order to preserve the efficacy of the leaves, must be kept free from dampness. The leaves are worth in Peru seventy-five cents a pound, and cost here one dollar.

The habit of the natives of the western countries of South America to chew the coca leaf, has given much interest to this plant; the dried leaves are chewed mixed with quicklime, which is said to make its flavor more sensible to the taste. In the same way the leaf of the betel-nut is used by the East Indians.

The leaves are called *cuca* by the Indians, and *coca* by the Spaniards. It has been estimated that cuca or coca is used by eight millions of the human race, consuming thirty millions of pounds per annum, by chewing the leaves made into a ball mixed with lime. The leaves are deprived of their stalks, two or three ounces of them being used during one day. It is a powerful stimulant to the nervous system, enabling fatigue to be borne with less nourishment and greater ease than usual. A case is reported by Whittingham,[1] in 1850, of two men being buried in a mine eleven days before they could be dug out, during which time they were kept alive by the small amount of coca they had with them.

So much vaunted is the coca as a stimulant to nervous energy, that the poet Cowley[2] represents an Indian chief as addressing Venus, thus:

> "Our *Varicocha* first this *Coca* sent,
> Endow'd with Leaves of wondrous Nourishment,
> Whose Juice suck'd in, and to the Stomach ta'en
> Long Hunger and long Labor can sustain;
> From which our faint and weary Bodies find
> More Succor, more they chear the drooping Mind,
> Than can your *Bacchus* and your *Ceres* join'd.
> The *Quitolta* with this provision stor'd
> Can pass the vast and cloudy *Andes* o'er."

It was used by the Indians of Peru in ancient times, being employed as an offering to the sun; it was also thought that unless the priest chewed these leaves during his ceremonies the gods would not be propitiated. It is still held in veneration, and is thought by the miners to have an effect in softening veins of ore if chewed and thrown upon them. As to the effect of this habit of chewing the leaves on the system, much difference of opinion exists; on the whole the opinion of Dr. Smith[3]

[1] Thompson's Cyclopædia of Chemistry. [2] Cowley's Works, London, 1700.
[3] Peru as It is. London, 1839.

is in accordance with most of the facts. He says: "When used in moderate quantity it increases nervous energy, enlivens the spirits, and enables the Indian to bear cold, wet, great bodily exertion, and want of food to a surprising degree with apparent ease and impunity." Sir Robert Christison, in a paper read before the Edinburgh Botanical Society, April 13, 1876, on this subject, narrates some experiments on his students and himself, showing the harmlessness of the drug.

Bouchardat[1] states that coca has rendered to therapeutics value almost equal to the cinchona bark, classing it as a stimulant to the nervous and muscular systems, and ranks it as such with tea and coffee. He terms it also a "substance d'épargne," or that which prevents the rapid waste of tissue. The leaf was first introduced into France by Joseph Bain, a "pharmacien," about 1869, from which he made an elixir and wine. Vin Mariani, of recent introduction into this country, is made from these leaves; we have also a fluid extract, etc.

Cocaine, the alkaloid, was discovered by Niemann in 1855; its chemical formula is $C_{17}H_{21}NO_4$; its physiological action is apparently identical with that of theine, caffeine, guaranine, and theobromine. Dr. Alex. Bennett[2] was perhaps the first to conduct a series of experiments with this alkaloid, his observations being made on the lower animals, and he concludes from these that: 1. Cocaine is a powerful poison, inducing a series of symptoms affecting the nervous, respiratory, circulatory, and vaso-motor systems, which terminate, if the dose be large enough, in death. 2. In small doses, cerebral excitement not followed by coma, and partial loss of sensibility. 3. In large doses it produces cerebral excitement, complete paralysis of sensibility, tetanic spasms, and death. 4. It paralyzes the entire posterior column of the spinal cord, *also the entire system of peripheral sensory nerves;* but the anterior columns of the cord and the peripheral motor nerves are not paralyzed. 5. It does not produce muscular paralysis. 6. It usually produces *contraction* of the pupils. 7. It produces an increase in the salivary secretion.

These conclusions were arrived at after experiments conducted on more than one hundred animals of different kinds. Dr. Ott, in THE MEDICAL RECORD, 1876, finds similar physiological effects, except that he noticed the pupil *to dilate;* this is in accordance with our present experience. It is interesting to note that the neutral principles contained in coffee, tea, and chocolate, beverages so generally in use, are almost identical in chemical composition, and similar in physiological action, to cocaine; and this fact may lead us to find in either theine, caffeine, or theobromine local anæsthetic properties similar to the alkaloid of the coca plant; if so, it would be much cheaper and more readily obtained. Cocaine is a very deliquescent substance and it is hard to obtain crystals, yet by patience they may be.

The experiments with the cocaine hydrochlorate, by applying it to mucous surfaces, as the conjunctiva, has been known of only about one month, and, as far as I know, the American surgeons have been among the first to operate with its use. The first reports of these cases are in this journal (page 438). Since then many more have been made, with almost universal success.

In addition to the three cases reported by me in a former number, I may cite the following that are of interest:

CASE I.—Ella M——, aged twelve, leucoma adhærens, with partial closure of pupil. Operation of iridectomy (artificial pupil) performed under cocaine. A two per cent. aqueous solution was used of the hydro-chlorate, dropped into the eye, eight drops during twelve minutes. At the end of six minutes, four drops having been used, the conjunctiva and nasal part of the cornea were insensible; in ten, the whole cornea was anæsthetic; two minutes later the operation began, when it was noticed that the edge of the pupil could be seen, showing the mydriatic effect of the drug. The introduction of the speculum and section of the cornea were absolutely painless. Fearing that the iris might be sensitive (as I had seen in another case), I injected two drops of the solution through the corneal wound on to the iris surface, when to my delight the iris section proved to be painless. The operation did well, and was performed on October 17th. The patient was seen to-day, with no irritation.

CASE II.—Mary H——, aged eleven; leucoma, with anterior synechia. Iridectomy done at my clinic at the Post-Graduate Medical School, October 17th. The solution of four per cent. strength was used. In three minutes after the first two drops were instilled the conjunctiva and cornea were almost anæsthetic. To insure success two more drops were used, and at the end of seven minutes the operation was begun. The introduction of the speculum and section of cornea were not felt, but when the iris forceps was introduced and the iris cut the patient showed some evidence of pain. It was this that led me to use the cocaine solution directly to the iris tissue, as in the case previously mentioned. This patient has thus far done as well as customary.

CASE III.—One of lachrymal stricture; James F——, aged twenty-eight. This being the first case where the skin played a part in the operation, the experiment was considered by me doubtful. However, the four per cent. solution was freely applied above the inner canthus and over the openings to the tear passages, and in six minutes the parts were sufficiently numb to allow of the slitting of the canaliculus without pain. An Anel's syringe, charged with eight drops of the cocaine solution, was introduced into the cut canal, and the fluid forced into the nasal duct as far as it would go. After waiting four minutes the No. 8 probe was passed without pain down to the roof of the mouth; this was then removed and a lead wire introduced, the patient all the time having no sensation. In twenty minutes after the injection the lead wire, which was purposely left, was felt for the first time.

CASE IV.—Michael R——, aged thirty-six; oritis syphilitica. Complaining of much pain; not relieved by atropine; was treated by instillation of cocaine, two per cent. solution, with relief of pain in twenty minutes after its first use. The drops were used, two every three minutes till eight had been applied. At the end of half an hour the pupil was noticed to be larger than when the experiment was begun. Pain returned that night, but not so severe as before.

CASE V.—Mamie B——, aged sixteen, West Harley, N.Y.; operation at New York Eye and Ear Infirmary. Diagnosis, irritable stump. Thinking that the anæsthetic effect of cocaine might go deeper by a freer use, I used in this case some twenty drops, with some benumbing influence, yet not sufficient to warrant an operation for removal of the eye, so after waiting twenty minutes I removed the eyeball in the "old-fashioned" way.

CASE VI.—The following experiments were made upon my own eye: October 16th, at the Academy of Medicine, Dr. Agnew put in two drops of a two per cent. solution (Merk's) in my left eye, and in ten minutes the conjunctiva was insensible. Not only that, but in twenty-five minutes the pupil was dilated, and remained so for twelve hours; the accommodation was also affected. This took place in thirty-five minutes after the use of the drug, Jaeger No. 1 being seen at thirteen inches only, when with the unaffected eye my near point was five inches. In the morning the accommodation was restored.

October 18th a two per cent. solution of cocaine, extracted from the leaves by Foucar & Co., New York, was used; hitherto all the experiments were made with Merk's preparation. Four drops of this solution were by Dr. Minor placed in my left eye, it being in a normal condition during five minutes. At the end of eight minutes the conjunctiva was held by fixation forceps and without my knowledge. The anæsthesia lasted twenty-two minutes;

[1] American Journal of the Medical Sciences, vol. lxxii.
[2] British Medical Journal, April 18, 1874.

in twenty-five minutes from the first drop the pupil was dilated three-fourths its size, and the accommodation interfered with. This lasted six hours, the pupil remaining dilated ten hours.

Case VII.—M. B——, thirteen years of age: strabismus convergens. Finding in some operations for squint that the cocaine acted on the conjunctiva well, but that when the muscle was hooked pain was experienced, it occurred to me well to inject under the conjunctiva, over the site of the muscle to be cut, a few drops of the anæsthetic fluid; this was done in this case, six drops being injected, and the usual six to eight drops being used on the surface of the eye. This procedure caused the pain to be entirely abolished. No bad after-effect occurred.

This mydriatic effect of cocaine is well marked and will make it a valuable contribution to our list, as ophthalmoscopic examinations can be made, and the inconvenience of atropine not be felt, the effect on the accommodation in the former being of such short duration. The chemical formula of atropia is almost identical with cocaine. The mydriatic effect of the cocaine applied to the eye in man differs from the effect noticed by Dr. Bennett in his experiments, where the drug was given by the stomach in animals, he finding a contracted pupil the rule. As to the action of the drug in producing anæsthesia of the surface both of mucous membranes and the skin, that is a point still to be worked out. Having already trespassed too long on your time, I will reserve further experiments with this drug for the future.

October 18, 1884.

THE THERAPEUTIC VALUE OF A SEA VOYAGE IN CERTAIN CASES OF CHRONIC DIARRHŒA.

By J. W. STICKLER, M.S., M.D.,

orange, n. j.

While crossing the Atlantic, I have had opportunity to observe that almost every voyager has, during the entire trip, been more or less troubled with constipation. This condition has been referred to by others, among whom I mention C. Pitfield Mitchell, M.R.C.S., who states in his monograph on the "Pathology and Philosophy of Sea-sickness," that of twenty-nine recorded cases—a fraction only of the number actually observed—constipation was present in twenty-eight; in the remaining one early diarrhœa and subsequent constipation.

Indeed this condition is so common that almost every one anticipating a sea voyage provides himself with a suitable cathartic. The ship's surgeon told me that the most common complaint of all the passengers, steerage and cabin, is constipation, and oftentimes it is of a very persistent character, not being relieved by salines, but requiring drugs more active. So far as my observation goes, it is most obstinate in those who suffer longest from nausea and vomiting.

Constipation in some instances may be due to the presence of the hydrated peroxide of iron in the water used for drinking and cooking. The presence of the iron is due to the fact that the water is carried in iron tanks, in which there is quite a thick deposit of iron rust which is mixed with the water by the constant motion of the ship.

In many cases, however, there is but little water used till after constipation is well established. Some form of alcoholic stimulant, or one of the natural alkaline waters, is used to assuage thirst, and crackers, toasted bread, with perhaps gruel and assorted fruits, to satisfy hunger.

After the sea-sickness and prostration accompanying it have passed away, both water and solid food are partaken of more freely, and the iron therein contained may act as an astringent upon the gastro-intestinal apparatus. H. M. Bracken, M.D., L.R.C.S., who has spent much of his time on the Atlantic Ocean, writes me as follows: Sailors would ask for "black draught," the formula for which is (according to the Brit. Pharm.):

℞. Infus. sennæ ..... 14 parts.
Magnesiæ sulph..... 4 "
Ext. glycyrrhizæ..... ½ part.
Tinct. sennæ..... 2½ parts.
Tinct. cardamom. co ..... 1¼ part.
M. Dose ℥ j. to ℥ ss.

(The fact that they asked for a cathartic of their own accord indicated that they must have been troubled with constipation, which a comparatively few hours at sea had produced.) Passengers were generally served with pil. colocynth co. (Brit. Pharm.) (Dr. Gregory's favorite pill), or pil. colocynth co. et hyoscyami (Dr. Christison's favorite pill).

The percentage of passengers and crew affected at the beginning of the voyage was usually large. The condition would last some time and be quite troublesome if no laxative were taken. One dose generally gave relief, and was often sufficient for a voyage of such duration as between England and New York. Persons from the tropics suffering from diarrhœa were generally benefited by a sea voyage.

The fresh, pure air from the sea, change of diet, change of habit, etc., brought about the improvement.

Very few cases of diarrhœa *originated* on board. These were usually the sequelæ of other diseases, or the result of gluttony. When from the latter cause, a good purgative and twenty-four hours of strict diet would relieve.

I have known others, who on land had tried various kinds of medication for the relief of diarrhœa, but without success, not being able to remove the malady till they went to sea.

Such patients, after being forty-eight hours on the water, either had one small alvine discharge daily, or every other day. This condition remained till a laxative or cathartic was taken.

Great benefit was derived when nervousness was associated with the intestinal trouble, especially that form of nervousness which is the result of over-mental work.

Reynolds says: "Patients near the coast should get to sea. When undertaking a voyage care should be taken that suitable provision and nursing should be provided; but this, though possible for people in good circumstances, is often impossible for poorer persons. There can be little doubt that being sent to sea *without comforts* in an *advanced* stage of the disease is an aggravation of their condition, and that they should be spared this by judicious early travel. It is to be hoped that the time will come when all ocean passenger steamers will specially provide for the comfort and care of sick passengers. Cabins with extra attendance, and good sick cookery, would be a great boon for the helpless invalid from diarrhœa and dysentery."

In addition to the class of patients referred to by Reynolds, *i.e.*, those reduced to a state of extreme exhaustion, there are patients of ample means who are rendered unfit for the daily round of active business life by a troublesome diarrhœa, which does not readily yield to drugs, but which in most instances would be greatly benefited or cured by an ocean voyage.

Copper as a Prophylactic in Cholera.—The *Petit Moniteur de la Médecine* recently issued an extra edition which was devoted entirely to a consideration of cholera. Among many anecdotes there appears the following: One day during the height of the cholera scare in Paris, a blind man was playing the Marseillaise on an old trombone in a courtyard. Joseph Prudhomme, who was afraid of the disease, called to him from his window to desist in the name of public health from playing that contaminating hymn. "My dear," interposed his wife, "did you not notice that the instrument is copper?"

THE INDUCTION COIL—ITS VARIETIES AND THE DIFFERENTIAL INDICATIONS FOR THEIR USE.[1]

By A. D. ROCKWELL, A.M., M.D.,

NEW YORK.

When solicited to contribute something to the annual meeting of this Academy along that line of research in which I have been interested for so long a time, I hesitated in the selection of a topic. Of material there is plenty, and of sufficient importance. The whole field of the physics, physiology, and therapeutics of electricity lies open before us. The comparative value of its three subdivisions offers a subject for discussion and the relation of experiences, while the differential indications for the use of these various forms—galvanism, faradism, and franklinism—is of still greater importance and even less understood.

Vital in interest as are each and all of these themes, and others that occurred to my mind, they seemed to be excluded from discussion here, since it has been suggested that whatever is presented should flavor somewhat of originality, or at least be not altogether hackneyed; and these topics have, one and all, been discussed at various times in the current medical literature of the day, and are more or less fully considered in many of the works devoted to electro-therapeutics. The laudable aspiration of this Academy, then, as attested by the prospectus lately issued, confirms the aphorism that "originality is a thing we constantly clamor for," as well as "constantly quarrel with." Unfortunately, however, pure originality in thought or methods of expression is the gift of but few. Old and long-forgotten ideas are being constantly rehabilitated and brought forward under the guise of new and advanced opinions. In this way, much that would otherwise be lost or fall short of its proper utilization becomes, through a more persistent and perhaps clearer presentation, a practical part of the world's integral store of knowledge. While, therefore, none of the facts in physics that I propose here to present are in any sense new, yet there has been no general appreciation of them, and but little knowledge, even among those who have been endeavoring in a blind sort of way to utilize them, that such facts existed.

As to the few statements that are made along the line of therapeutics, the most that I can say of them is that they are the result of much experience and of very many carefully recorded observations, and if presented with any measure of clearness ought to be of some little service to those who are interested in but who have given little thought to the matter. But to my theme. There are two kinds of electro-magnetic machines that are presented to the medical man for therapeutical purposes. The first is termed a *separate* coil, and the second a *continuous or single* coil apparatus. The separate coil apparatus is the one most commonly used and the one most generally understood. The separate coil is the variety described and illustrated in every text-book of physics, but not in sufficient detail to make clear its mechanism when used for medical purposes. Craving the indulgence of those who may be thoroughly informed on these points, and who may therefore regard as primitive the remarks that follow, let me by the aid of the accompanying diagram (Fig. 1) describe the course and influence of the electric current in an ordinary separate coil faradic apparatus.

All induction machines are composed of not less than two coils. The first or primary coil consists of a large, well-insulated wire surrounding a bundle of soft iron wire, which forms a magnetic centre. Over this first or primary coil is wound a coil composed of several convolutions of fine, well-insulated wire for the induced current. The terminals of the first or primary coils of wire are united, one end to the battery that operates the coil, and the other to the part of the automatic rheotome according to the following description. As the battery is *the* important factor, let us start from it and follow the connections and action of the combinations that produce the effect:

The positive pole (P) of the battery is connected with the governor marked A (Fig. 1). The negative pole N of the battery is connected with the first end of the primary coil, while the last end of the primary coil is

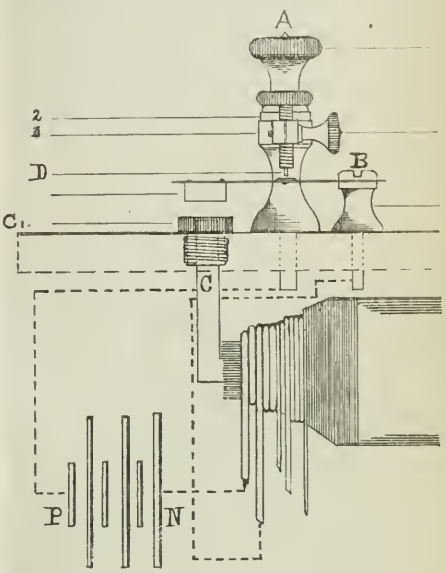

Fig. 1.

connected with the spring support B. The electro-motive force is conveyed from the battery through the primary coil to the spring support B (rheotome), thence to the platina-pointed screw of the governor D, and lastly to the battery, making the complete circuit.

In the centre of the coil and surrounded by the soft iron wires is placed a soft iron rod. One end of the rod is bent at right angles, so that the hammer on the spring is directly over and can move toward this soft iron rod, marked C. When the vibrating spring is resting against the platina-pointed screw D and the battery is connected with the coil, the current, as it passes over the wire of this primary coil, renders magnetic both the centre bundle of soft iron wires and the soft iron rod.

The magnetism is of sufficient force to attract the soft iron hammer on the spring, and draw it down or near to the magnetized rod C.

This movement of the spring severs the connection between the spring and the platina-pointed screw D and opens the circuit. The soft iron rod, therefore, loses its magnetism. The spring ceases to be held down, its tension being sufficient to raise it to a horizontal position, where it again rests in direct contact with the platina-pointed screw D. Again the circuit is closed and the process as described is repeated with inconceivable rapidity. By the action of the battery current as it is conveyed over the primary coil, and the influence of the magnetized bundle of soft iron wires, a current is induced upon the second coil of fine wire which surrounds the primary coil. This power of induction can be established to the fifth and sixth coil, and further if the magnetic field is properly arranged.

In the ordinary form of induction coil just described, the terminals of the secondary or fine wire coil are free and in no manner connected with the primary circuit.

[1] Read before the annual meeting of the American Academy of Medicine, at Baltimore, October 28, 1884.

The influence of magnetism produces a current which we call pure induced.

In the continuous coil apparatus, on the contrary, we not only receive the inductive influence, but the primary influence as well, since it is carried over in combination with the induced currents. Although called a continuous coil, it is really made up of several distinct coils, and each successive coil increases in length but decreases in thickness. These coils are wound over each other, and are tapped at different portions of their length, but unlike other forms, they make direct connection with each other. This accounts for an apparent contradiction of terms that might prove confusing.

These coils are for convenience of illustration represented by the upper straight lines ⎯, ═, ≡, ≣ (Fig. 2), termed respectively the primary, first, second, and third induction coils. The letters A, B, C, D, E represent the different posts of the continuous coil apparatus to which the conducting cords are attached, while the numerals 1, 2, 3, 4, etc., indicate the combinations by which are obtained ten different qualities of current. The short line marked 1, starting from A, represents the current from the short, thick, primary coil marked ⎯. Second line (2), current from the primary and first (═) induction coils combined. Third line (3), current from the primary and first and second (═, ≡) induction coils. Fourth line (4), current from primary, first, second, and third (═, ≡, ≣) induction coils. Fifth line (5), current from the first induction coil only. Sixth line (6), current from the first and second induction coils. Seventh line (7), current from the first, second, and third induction coils. Eighth line (8), current from the second induction coil. Ninth line (9), current from the second and third induction coils combined. Tenth line (10), current from the third induction coil only.

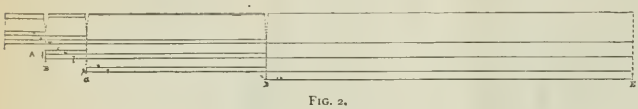

Fig. 2.

Therapeutical considerations.—When we consider the many combinations that are possible in the continuous coil apparatus and the different qualities of current that result therefrom, its general superiority over the separate coil is sufficiently evident; and this superiority becomes more marked if we examine into the varied physical and physiological effects produced by these combinations.

Our object of inquiry, however, is not as to the relative merits of different machines, but as to the comparative value of and the differential indications for the use of the various combinations of the continuous coil apparatus. This point of inquiry, although less important than when it relates to the two forms of dynamic electricity, is yet of no little account, and in some respects has been found to be more difficult of solution.

Notwithstanding the many qualities of current that are derived from the continuous coil, I have, after much observation, reduced to three the number of combinations that seem to be worthy of differential consideration.

Every therapeutic result that can be obtained by any of the ten combinations heretofore considered, will in all probability result from the use of some one of the following:

1. The current from the primary coil as represented by the line marked 1 (Fig. 2).

2. The current from the primary and the first and second induction coils in combination, as represented by the line marked 3.

3. The current from the primary and the first, second, and third induction coils in combination, as represented by the line marked 4.

The primary coil yields a current of large quantity but of small tension, owing to the fact that the wire of which the coil is composed is short and thick. It is worthy of note, however, that this current has considerable chemical power. It will burn iron or steel, giving forth a bright deflagrating spark, and will readily electro-plate, an effect not obtainable with any of the induction coils, either alone or in combination with each other. This current is apparently very weak, and induces but slight muscular contractions in the healthy person. In occasional pathological conditions, however, this mild current acts with unexpected energy, producing muscular contractions far exceeding in vigor those that are called forth by the stronger action of the induction coils.

On account of its mild but efficient action the current from the primary coil is preferable for applications to the head and the more sensitive portions of the body, and it will as a rule relieve pains of a true neuralgic character, and especially when great tenderness exists along the course of the nerve, far more effectually than the current from any of the induction coils. It is impossible to account for this frequently observed fact, without it be ascribed to a combination of the battery and the inductive influence. When dealing with an agent so subtle and so little understood as electricity, it is difficult to express one's meaning in terms altogether satisfactory, but that such a combination is active and effective is evidenced by the readiness with which electrolytic effects are produced. Asthenopia is a symptom that I have known to be greatly relieved and even cured many times by electricity, but more especially through the use of the primary coil. The tired, aching eye is both temporarily rested after each sitting and permanently strengthened by continued treatment. There seems to be little appreciation, either among ophthalmologists or general practitioners, of the great relief that may follow this treatment in the many cases where the eyes ache severely, if used even for a little time before breakfast or at twilight, or where neuralgic pains exist in or near the eye, or where there is annoyance from muscal volitantes.

As we include in the circuit with the primary the various induction coils, the current increases in strength with each coil that is added. With the addition of the first induction coil a much greater strength is apparent, but the combination has no marked physical or physiological effects that need detain us. By including also the second induction coil in the circuit, however (line marked 3, Fig. 2), we obtain a current of a peculiar and unique quality. Like the primary coil, it will electroplate, but unlike it, it will not burn steel or iron. The peculiarity of this combination of the coils is that the maximum of power to contract muscular tissue is here obtained. Each additional coil now that is attached simply gives a decreasing contractile power. Why the maximum of current strength is reached in the combination of the primary with the first and second induction coils it is difficult to say, excepting as we ascribe it to the law of harmony or polarization that is brought about by properly conditioning the magnetic centre of the helix, the several coils composing the helix, and the battery influence acting upon the coils. The current from this combination is not at all pleasant; it is keen and cutting in character, and with its strong contractile properties it is peculiarly adapted to those cases where powerful impressions are called for. Hence in not a few cases of paralysis where the response to galvanism is perfect, but where there is a diminution of farado-muscular contractility, I have found it preferable to any of the other qualities of current to be derived from the continuous coil apparatus.

In superficial forms of anæsthesia it is, perhaps, in no way superior, but in certain persistent and more deeply seated forms of lost or perverted sensibility it is decidedly more efficacious than other combinations. Its greater contractile power over muscular tissue, both voluntary and involuntary, renders it most efficacious in

cases of menstrual suppression, and also for atrophied conditions of the uterus, for which so much has been done by electrical methods of treatment. In cases of dysmenorrhœa, as well as in the various neuralgias, my experience leads me to exclude its use. Faradism has been used, and with success, to destroy the fœtus in extra-uterine pregnancy. While I greatly prefer the galvanic current, having always used it without the slightest ill effect, yet if the faradic is employed I should not recommend the current from the coils now under consideration, but the one presently to be described; for with this latter form we obtain effects equally destructive to the fœtal life and with less violence to the contractile tissues of the mother. There are several other differential points connected with the use of this series which suggest themselves, but they are of minor importance.

When we include in the circuit not only the primary and the first and second, but also the third induction coil as represented by the line marked 4, effects are obtained more interesting and satisfactory than from any of the other combinations.

These effects are pre-eminently tonic and sedative in character, and give for this quality of current a range of usefulness wider than can be ascribed to the others. There are but few, in all probability, who at this day are unfamiliar with the term general faradization, and who do not understand that by it is meant the application of the faradic current to the entire surface of the body, from the crown of the head to the soles of the feet. It is in the operation of general faradization, when we desire to obtain the best constitutional tonic effects that electricity is capable of giving, that we resort to this combination of the primary and induction coils. Its action on the motor and sentient nerves is less severe, and its general effects far more agreeable. For the relief of that great army of symptoms that are so familiar and so perplexing to those who have had much to do with neurasthenic cases, there is, according to my experience, nothing to be compared with it. Even the galvanic current by the method of central galvanization, so important in its direct effect upon the central nervous system, falls short of the therapeutic results that follow well-directed applications of general faradization. When persistent failure follows endeavors along this line of electrization, the cause of failure must be ascribed to hasty and faulty methods of administration. In no department of therapeutics is it of more importance to be thorough in detail. He only will achieve the best results who appreciates this fact, who is willing to inform himself as to the *modus operandi* of the methods, and who will devote in individual cases a reasonable degree of time and patience in carrying them out.

An Antipyretic Formula.—The following is recommended by Dr. de Giovanni as a substitute for quinine, in which the latter is ineffective or injurious in its effects (*Rivista Clinica*, No. 8, 1884): Ergotine (Bonjean), fifteen grains; tincture of valerian, half an ounce; water, three ounces; to be taken during the height of the fever or in the period of remittance. Usually the good effects are obtained after one or two doses, but the remedy should be continued for some time after the subsidence of the fever. In rebellious cases the author substituted with benefit cherry-laurel water, one-half to one drachm, for the valerian. The best results were obtained in intermittent fevers, but good effects were seen also in remittents, in the hectic of incipient phthisis, and even in puerperal fever.

Bicarbonate of Soda in Iodoform Poisoning.—Dr. Behring states that bicarbonate of soda is an antidote in poisoning from iodoform. Since the latter drug is eliminated in the urine as an iodic salt, the author assumes that it abstracts alkalies from the blood. By supplying the alkali thus withdrawn from the blood he believes that the system may acquire a special toleration for iodoform.—*Rivista Clinica*, No. 8, 1884.

Progress of Medical Science.

German Measles.—It appears to be a somewhat general opinion that Rötheln, or, as it is not infrequently called, German measles, is a disease of such minor importance as to be unworthy of scientific research; but a disease, the victims of which succumb as early as the fourth day, must be of sufficient importance to demand our attention and the best efforts of our armamentarium. Dr. W. A. Edwards, during the winter and spring of 1881–2, studied in the Philadelphia Hospital over one hundred cases of the disease, and the results of his observations he details in a paper in the October number of *The American Journal of the Medical Sciences*. As regards the diagnosis, he says the eruption appearing on the third day, first in the face, its rapid extension, its gradual shading off into the surrounding skin, its elevation, more particularly in the centre of the patch, which is also the brightest in color, together with the fact that desquamation first shows itself there, are all points which, as far as the eruption is concerned, render the diagnosis plain; furthermore, the rash almost at once occupied the whole body, and never presented a crescentic outline. The extreme drowsiness during the eruptive stage is a symptom upon which Cheadle lays some stress. It is Dr. J. M. Keating's experience that however severe the attack may be, or how diffused the eruption, the contour of the face is never lost, and that by looking properly you can always see the zygomatic arch; this, he observes, is always obliterated in cases of either measles or scarlatina that are severe in character. Sore throat was always present; in scarlatina it is directly in proportion to the type and severity of the disease; the more laryngeal character of the cough in Rötheln is also worthy of note. The pulse remains low, that is, much lower than a case of like severity of either measles or scarlatina. The fact that Rötheln propagates itself, and never gives rise to either measles or scarlatina, and, moreover, does not protect from these diseases, is a further diagnostic point that should claim our attention. Dr. Edwards highly recommends the application of oleaginous preparations to the skin during the stages of eruption and desquamation; in the former stage for the comfort of the patient, and to allay itching and aid in the reduction of the temperature; in the latter, to prevent contagion, as all of his cases underwent desquamation, and in all probability the contagion is carried by these fine scales.

Iodoform-forming Bodies in the Expired Air of Diabetics.—As is well known, Petters, Kaulich, and others have found acetone, revealed by its peculiar odor, in the expired air, the urine, and the blood of diabetics. Later investigations have proved its presence in the urine by chemical reactions, but methods for recognizing it in the expired air were less available. Several new acetone reactions having been recently discovered, Dr. Nobel attempted to reach results more accurate than have been hitherto obtained. The urine of the diabetic patient contained no acetone on examination, but some days after an exclusive fish-diet was begun it contained large quantities. The expired air was thus examined. It was first conducted into a Wolff's bottle, filled with distilled water, and after half an hour a solution of iodine in iodide of ammonium and liquor ammoniæ was added. By the next day a yellow precipitate was seen at the bottom of the flask, which on microscopic examination showed the iodoform tablets most clearly. On the other hand, the urine of another diabetic patient, which only gave a weak acetone reaction, showed only a slight separation of iodoform. On another occasion the air was passed through the water for an hour, the latter was distilled for six hours in a water bath at 146.4° F., and the distillate was divided into three equal portions. To one the above-mentioned test solution was added, and a copious precipitate of iodoform obtained. To the sec-

ond a few drops of mercuric chloride were added, and then enough caustic potash to render it alkaline; it was then filtered and ammonium sulphide added; this caused a black precipitate of sulphide of mercury (Gunning's reaction). The third portion yielded a positive result with sodium nitro-cyanide and liquid ammonia (the acetone test of the author). No doubt remained that the iodoform-making substance was acetone. Continued distillation for an hour gave no more acetone, though the iodoform reaction revealed $\frac{1}{10000}$ milligr. On another occasion the distillation was made at the temperature of 176° F.; and after twelve hours the neutral distillate, which gave distinctly the iodoform reaction, was treated with spongy platinum, and the presence of acetyl-aldehyde at the beginning of oxidation was proved by the reduction of ammonia-silver solution, and by the color-test of the author (sodium nitro-cyanide, caustic potash, and acetic acid). By further oxidation acetic acid was formed, which reddened blue litmus-paper held over it; by careful neutralization with very dilute caustic soda, a red color, which was destroyed by dilute sulphuric acid, was obtained with ferric perchloride. Thus, beside acetone, ethyl-alcohol was found in the air expired by this patient. Regarding the destiny of alcohol in the animal organism, according to some it is oxidized for the most part, and, therefore, must have a nutritive value; while, according to others, the greater part of it is excreted, unaltered, by the kidneys, skin, and lungs. However this may be, it is evident that no conclusion can hence be drawn as to its behavior in the bodies of diabetics, in whom the oxidation-processes are altered so much owing to irregular tissue-changes. The alcohol formed in such subjects may possibly be excreted unaltered for the most part, which would agree with the above results.—*London Medical Record*, August 15, 1884.

Cholecystotomy.—In *The American Journal of the Medical Sciences* for October, 1884, Drs. J. H. Musser and W. W. Keen publish an article on cholecystotomy, in which they relate two new cases, with a table of all the hitherto reported cases, thirty-five in number. The first case was that of a man, aged thirty-two, who had had attacks of biliary colic for five years, followed by jaundice, until he was reduced in strength, and had chills and fever threatening life. Dr. Keen attempted cholecystotomy, the incision being made over a region of dulness believed to be the gall-bladder. This dulness was found to be due to an inflammatory mass, which glued together the gall-bladder, colon, and intestine. No stone could be detected. The wound was closed, and recovery ultimately followed a course of Hathorn water at Saratoga. The second case was also that of a man, aged thirty-one, with acute gastro-intestinal catarrh, followed by jaundice, enlarged gall-bladder, and symptoms of internal suppuration. The enlargement of the gall-bladder was demonstrated by the hypodermic needle, but the fluid was not bile. Dr. Keen performed cholecystotomy, using a large hollow-handled spatula to drain off the twenty ounces of fluid contained in the gall-bladder. The gall-bladder was found to be seven inches in depth, but neither by finger nor probe could any gall-stone or the orifice of the duct be found. A biliary fistula was established, and bile was discharged through it the next day. The patient died a week later of exhaustion. The post-mortem examination revealed inflammatory closure of the cystic and common ducts at the mouth of the gall-bladder and at the duodenum. Dr. Musser in his medical comments analyzes at length the causes, symptoms, and diagnosis of biliary obstruction, under the heads of jaundice, tumor, pain, and suppuration, especially in relation to gall-stones and other foreign bodies and diseases of the ducts. He points out the means by which a just conclusion may be reached, and that cholecystotomy should be resorted to early in the case rather than wait till the blood is disorganized and the liver softened and made functionally useless. Especially is this true in view of the low mortality of the operation, there having been (excluding Gross' incidental case) only nine deaths in thirty-four operations, and of the fact that Mr. Tait has done thirteen operations, by far a larger number than any other operator, all of which have been successful. In his surgical comments, Dr. Keen discusses the surgical means of diagnosis by aspiration, with or without probing through the canula, and by acupuncture, both of which, when properly done, he commends. He also strongly urges an early laparotomy, followed at once by cholecystotomy, if found advisable, and condemns the attempt to provoke or to wait for adhesions. Indeed, upon this disregard of adhesions hinges the whole of our modern progress in abdominal surgery. He points out that to Bobbs, of Indiana, and to Sims, both American surgeons, is due the credit of first performing and practically perfecting the operation. He advises the formation of a biliary fistula, rather than sewing up the gall-bladder, and disapproves, as a rule, a removal of the gall-bladder, as adding a new and usually a needless danger.

Dyspeptic Coma.—Dr. Riess has observed a number of cases resembling in their principal features the picture depicted by Kussmaul of diabetic coma. But in no instance was there any glycosuria, the coma occurring with anæmia, nephritis, and carcinoma of the liver and stomach. In almost every case the chloride of iron test gave negative results, showing that the trouble was not due to poisoning with acetones. The author concluded that the symptoms of diabetic coma, for which he proposes the name of dyspnœic coma, may be also excited by a falling off in the proportionate number of red blood-corpuscles. Dr. Litten has observed the characteristic chloride of iron reaction of the urine in twenty-five non-diabetic patients, and concludes that it may be found exceptionally with any disease. In only one of these cases did he observe the dyspnœic coma of Kussmaul. He saw, however, several cases in which there was the peculiar odor of the breath and a soporific condition, but without any of the respiratory disturbances described by Kussmaul. He thought, nevertheless, that the two conditions were essentially the same, and were caused by poisoning from some substance produced in the digestive canal. This is probably the same substance to which is owing the peculiar odor of the breath and the characteristic reaction of the urine. This was supposed to be ethyldiacetic acid, but Frerichs denies the identity of the two substances.—*Allgemeine Medicinische Central-Zeitung*, No. 68, 1884.

The Physiological Action of Digitalis.—In the October issue of *The American Journal of the Medical Sciences* Dr. Nickles, of Cincinnati, summarizes the present state of our knowledge of the physiological action of digitalis. The doctrines now universally taught regarding the action and uses of digitalis differ in a number of important points from those held two decades ago. Then we were taught that digitalis is essentially a sedative, affecting strongly the nervous system, thus causing feeble and slow heart action. Now the latest authors teach that the nervous system is only secondarily affected, while the heart is directly influenced, its action becoming more powerful though slower. Twenty years ago we were taught that digitalis is a diuretic, directly acting upon the kidneys, thus producing in many diseases a greater secretion of urine. To-day we are told that digitalis does not act upon the kidneys at all, and only secondarily affects the secretion of urine by causing a change in the systemic circulation. In one point, there is universal agreement, that digitalis recklessly used may produce the most disastrous effects, and that these may occur quite unexpectedly in consequence of cumulative action. But not only in regard to the *modus operandi* do present authors differ from their predecessors, but also as to the therapeutic indications. Two decades ago digitalis was held to be indicated when the heart's action is too powerful; now we are informed that it is useful only when the heart's action is too feeble. Then author

taught that digitalis will control, and hence favorably influence, a hypertrophied heart, while present writers contend that every disease of the heart attended with excessive action is aggravated. It was held for a century that digitalis, though not eminently useful, is still often of great service in dropsy dependent upon organic disease of the kidneys; but now we hear that in diseases of the kidney, attended with diminished diuresis, it is almost always useless, and always exceedingly dangerous.

Mumps as a Cause of Sudden Deafness.—Disease of the ear during the progress of acute infectious disorders is a not infrequent occurrence. Especially are suppurative inflammations of the middle ear common during the progress of scarlet fever, and non-suppurative inflammations are a frequent attendant upon the progress of measles. The nature and treatment of these ear diseases are well understood. But occasionally during the progress of mumps a sudden and complete loss of hearing occurs which is not so well known, either as to its nature or its treatment. A paper on the subject from the pen of Dr. Leartus Connor, of Detroit, which appears in the October number of *The American Journal of the Medical Sciences*, gives the following conclusions: 1, Parotitis in some rare cases produces complete deafness; 2, this deafness is usually attended with all the evidences of disease of the labyrinth; 3, these show that it sometimes begins in the cochlea, but more frequently in the semicircular canals; 4, owing to the lack of early observations and treatment it is impossible to say that it is not transmitted through the middle ear from the parotids to the labyrinth; 5, the history of some of the cases would seem to suggest that such an origin was possible; 6, this possibility renders it very important that every case of deafness during an attack of mumps be at once carefully examined, so as to settle the question; 7, this possibility offers the only hope for the successful treatment of these cases so as to prevent deafness. Thus, if there be a middle-ear disease, we might hope that revulsive and counter-irritant treatment would arrest the disease and save the labyrinth; 8, as to treatment of the labyrinthine disease nothing has thus far been devised that has produced any satisfactory result.

Grave Nervous Symptoms Occurring in Typhoid Fever.—Dr. Baas relates the case of a boy eight and a half years old, who was suffering from typhoid fever. At the twentieth day, when the fever was at its maximum, the child passed some bloody stools, and at the same time fell into a state of complete cerebral torpor. The patient gave no signs of consciousness, the pupils were contracted and responded very sluggishly to light, and there were several convulsive attacks limited to the right side of the face. The following day there was paralysis of the right facial nerve and of the arm on the same side. The fever began to subside at this time, consciousness slowly returned, and the paralysis disappeared. But with the return of consciousness the child was found to be aphasic and agraphic. He understood what was said to him, but was unable to find the words to reply. On attempting to write he could only trace some meaningless figures which he himself recognized as expressing nothing. For a few days he was unable even to indicate his desires by appropriate gestures. He could not count, but would point with his finger to the number which he was not able to articulate. Five weeks after the beginning of paralysis he began to speak, articulating first the vowels and later the consonants. One month later he had entirely recovered. These symptoms seemed referrible to lesions in the third frontal convolution on the left side, and in the motor centres of the cortex. The author believed that they were caused by a capillary apoplexy. —*Archives Générales de Médecine*, September, 1884.

The Varieties of Purpura.—The pathogenesis of purpura is as yet involved in considerable obscurity. In a recent study of the subject, Dr. Leloir (*Annales de Dermatologie et de Syphiligraphie*) recognizes three main groups of this affection: *A*. Purpura from modification of the vessels.—1. From perturbation of the capillary circulation, whatever its origin, leading to active or passive hyperæmia, producing hemorrhage by diapedesis or by vascular rupture. 2. *Purpura télangiectasique* of Cornil. 3. Purpura from primary alteration of the vascular walls, and consecutive rupture of these walls. *B*. Purpura from modifications of the blood.—1. Too great fluidity of the blood (purpura by diapedesis). 2. From vascular obstructions determined by certain elements contained in the blood leading to the formation of thromboses and embolisms. This purpura might occur from simple diapedesis; it is more often hemorrhagic infarction of the skin. *a*. From formation of clots in blood-dyscrasiæ. *b*. From embolism formed by white corpuscles (leucocythæmia, etc.). *c*. From embolisms formed by bacteria or micrococci (septic diseases, etc.). *d*. From embolisms formed by altered blood-elements. *C*. Purpura nervosa. In practice, however, many cases will not fall completely into either group; very often the origin seems to be complex. Alteration of the blood, troubles of the circulation, vascular lesions, disturbances of innervation, all causes of cutaneous hemorrhage, may coexist in the same subject. In all probability, even dyscrasic purpura may be in certain cases the origin of secondary vascular lesions, of secondary endarteritis. And it is probable that alteration of the blood often modifies the action of the vaso-motor nervous apparatus, central or peripheral. In studying a case of purpura, it must not be forgotten, then, that its pathogenesis may be complex. The relative importance of the different causes must be sought; and an attempt must be made to determine the relations between the determining primary or predisposing causes and the occasional or secondary causes.

Iodized Collodion in Erysipelas.—Dr. Humphreys, of Texas (*Nashville Journal of Medicine and Surgery*, September, 1884), has used for the past five years iodized collodion as a local application in erysipelas. He has had uniform success with it, even in quite obstinate cases. Constitutional treatment is, however, not neglected by him. The collodion is applied with a feather or camel's-hair brush, as often as desirable (?). Upon evaporation of the ether there is a feeling of coolness and ease, after days and nights of suffering. The following formula for making the iodized collodion is taken from *Walzl's Photographic Rays of Light*, January, 1878.

℞. Sulphuric ether ..... ℥ x.
Alcohol, absolute ..... ℥ x.
Gun cotton ..... ʒ ij.
Mix, and when dissolved add
Iodine ammonium ..... grs. 80.
Iodide cadmium ..... grs. 40.
Bromide cadmium ..... grs. 40.
Mix, and bottle tightly for use.

As the salts of cadmium may not be readily obtained in country drug stores, it is highly probable that two drachms iodide ammonium and two scruples bromide potassium or ammonium added to the first three articles would prove as efficient as the formula given above.

Atropine in Acute Otitis Media of Childhood.—Dr. Miot has obtained excellent results in earache of children from atropine. The children to whom he gave it were very subject to coryza, and the inflammation would usually pass from the nose to the fauces and middle ear. But when atropine was given at the very commencement of the rhinitis the children were spared the pain of the otitis. For a child he used a solution of sulphate of atropine, 1 milligramme to 80 grammes of water ($\frac{1}{80}$ grain to 20 drachms), the dose of which was a teaspoonful repeated from two to four times a day at intervals of two or three hours. For adults he prescribed a dose of double this strength. The treatment was continued usually for two or three days.—*Journal de Médecine et de Chirurgie Pratiques*, September, 1884.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, November 8, 1884.

THE HISTORY AND PROPERTIES OF COCAINE.

WACKENRODER and Johnston expressed the belief, as long ago as 1853, that an active alkaloid existed in the leaves of erythroxylon coca. Gadeke first isolated it, but it was not till 1860 that Niemann (*Ann. Chem. Pharm.*, 114, 213) announced its physical properties and gave it the name of *cocaïn*. A little later Losson found in coca leaves another, apparently inert, volatile base, which he called hygrin (*Ann. Chem. Pharm.*, 133, 351). This latter chemist states that in the best leaves the amount of cocaine was at most one-fifth of one per cent., and in the poorer kinds as little as one-sixtieth of one per cent.

Cocaine crystallizes in large four to six-sided colorless prisms. It has a bitter taste, benumbing the tongue, a strongly alkaline reaction, and melts at 98° C. It dissolves in 704 parts of water at 12° C., easily in alcohol, and more easily in ether. Its composition, as determined by Losson, is $C_{17}H_{21}NO_4$.

Cocaine unites easily with dilute acids to form crystallizable salts, which are soluble in alcohol but not in ether.

The salts which the industry of chemists have already prepared are the muriate ($C_{17}H_{21}NO_4HCl$), the sulphate, nitrate, tannate, and oxalate. Besides these there have been prepared double salts of cocain-platinum chloride ($C_{17}H_{21}NO_4HClPtCl_2$) and of cocain-gold chloride.

By decomposition with strong acids a new base has been formed out of cocaine, which is called ecgonin.

A test given for watery solutions of muriate of cocaine is picric acid, which throws down yellowish precipitate.

The alkaloid cocaine has not been used medicinally to any great extent, but its physiological action has been studied by a number of observers.

For man the dose runs from one-sixth to two grains. Its lethal power is slight and its action is not cumulative (Husemann). Von Anrep found (*Archiv. ges. Physiol.*, 21, 38, 1880) that the cocaine could be taken daily for a long time without producing any notable disturbance, and he concluded that its action was not cumulative. Schroff, who in 1862 made the first experiments upon man with cocaine (*Zeitschrift f. Wien. Aerzte*, 30–34), found that in large doses it caused vertigo, lassitude, slight deafness, disturbance of memory, and of co-ordination of thought.

Other experiments and observations by Froumüller (*Prag. Vierteljahrsschr.*, 179, 109, 1863), Jarchanoff ("Cocain and Diabetes, Petersburg, 1872), and Ploss (*Zeitschr. Chir.*, 222, 1863), appear to show that cocaine is a narcotic, having a primary stimulating action upon the brain, and being analogous in properties to cannabis indica. Froumüller, in fourteen cases, was able to produce sleep by giving large doses (up to five grains). Ploss reports the case of a druggist who took about twenty-two grains of cocaine in a glass of beer. He slept quietly for some hours, then awoke with powerful abdominal gripings, burning and dryness of the mouth, and thirst. He vomited any liquid drank. He suffered from vertigo, feebleness, and aneuria for twenty-four hours. The heart's action showed no disturbance, and his mind was not disordered. The case is instructive as showing that cocaine is probably not a very poisonous drug to men, and that in large doses its narcotic action is immediate.

Among animals it has been found that frogs are more susceptible than warm-blooded animals, and that carnivora are more sensitive than herbivora.

The fatal dose for a dog is from three to five grains (Danini: "Ueber Physiolog. Wirkung und Therap. Anwendung des Cocains," St. Petersburg, 1873). Rabbits are killed by doses of 0.1 gramme per kilogramme of animal, according to Von Anrep.

The physiological effects of cocaine externally and internally have been studied by the authors already quoted, and by Nikolsky ("Beitrag. zur Cocaïn Wirkung auf den Thier Organismus," St. Petersburg, 1872); Isaac Ott (Moréno y Mäiz: "Recherches Chim. et Physiol. sur l'Erythroxylon Coca du Pérou et la Cocaïne," Paris, 1868); by Danini ("Ueber Physiol. Wirkung u. ther. Anwendung des Cocaïns," Charkow, 1873); Bennett ("Report on Antagonism of Drugs," 1875); and by Rossbach ("R. and Nothnagel's Handbook of Therapeutics"). An excellent review of the contributions of these authors, to which we are indebted, is given in Husemann and Hilger's "Die Pflanzenstoffe," Berlin, 1883, from which we summarize the knowledge so far gained of the properties of the drug.

Locally, it produces the effects upon skin and mucous membrane which have been already described in THE RECORD, and need not be repeated now. Moréno, in 1868, showed that local injections abolished reflex movements for a time, and Von Anrep, in 1880, showed that the sensibility of the skin was abolished *when hypodermically injected*, and that of the tongue when touched with strong solutions. The same author applied a solution containing one-half a milligramme to the conjunctiva, and found that it caused a temporary dilatation of the pupil, which was increased by adding atropine. Strangely enough, Anrep did not note that the conjunctiva was insensible, or if so, did not appreciate the practical significance of the fact. As Nikolsky found that the pupil is still dilated by cocaine after section of the sympathetic, it is inferred that the drug does not act upon the iris through that nerve.

Cocaine given internally in small doses to warm-blooded animals stimulates the nerve-centres, acting most plainly upon the higher psycho-motor cells of the brain, then upon the medulla oblongata and the cord. It seems especially to affect the action of the semicircu-

lar canals, causing vertigo, and in dogs, at least, disturbances of equilibrium and rolling movements. The pupil is dilated. A lengthening in the time of muscular contraction, claimed to exist by Ott, Buchheim, and others, is denied by Nikolsky and Anrep. Respiration is hastened and labored in warm-blooded animals; in fatal doses the breathing stops before the heart-action. Upon the heart moderate doses of cocaine in warm-blooded animals lessen the inhibitory action of the vagus and increase the rapidity of the beat without impairing its strength. Moderate doses appear also to raise arterial pressure, but in medicinal doses the cocaine does not greatly affect the vaso-motor system. Moderate doses increase intestinal peristalsis, while large doses lessen it and seem to produce a venous congestion of the walls.

There is a decrease in the secretion of saliva and of mucus, while the urine does not seem to be much affected, except in toxic doses.

So far as the local anæsthetic effect of cocaine is concerned, it seems to have been independently noticed by several persons, as we have indicated above. The practical application of this knowledge, however, is only of very recent date.

THE TENEMENT-HOUSE CIGAR BILL AND THE FACTORY NUISANCE.

THERE have been two recent decisions on health questions which deserve attention. The first of these is the judgment of the General Term of the New York Supreme Court, holding that the Tenement-house Cigar bill is unconstitutional. This law was passed at the last session of the Legislature and took effect immediately. By its provisions it prohibited the manufacture of cigars in all tenement-houses occupied as the home or residence of more than three families living independently of one another and doing their cooking on the premises. Two days after the passage of the act, Peter J——, who occupied seven rooms on the first floor of a tenement-house and manufactured cigars in one of them, was arrested for breaking the law. He was unable to procure bail and was committed to prison. A writ of habeas corpus was then sued out in his behalf, but was dismissed, and an appeal from this decision has been up for review at the General Term of the Supreme Court, where it was reversed and the law declared unconstitutional. The grounds for this decision are that the labor of the poor man is his only property and as much entitled to protection as any of its accumulations; that this law suddenly deprived him of the free use of this labor, and in effect seized private property without just compensation. Such a result is against the Constitution of the State, and any law which allows it must be unconstitutional. The opinion goes on further to say that the ostensible object of the bill, viz., to secure better health, as declared in the title of the bill, is a mere pretence, and that the real object is to "suppress and restrain such manufacture in the cases covered by the act, for the purpose of preventing successful competition, injurious to other modes of manufacturing the same article."

The judges find reasons for this belief in the very face of the bill, and they certainly make out a strong case. They say that tenement-houses where the cooking is not done on the premises are exempted, and that the most thronged and over-crowded tenements, which are occupied largely by persons who live from hand to mouth and by beggary, can manufacture cigars without interference. Also the first floor of the tenement-house is excepted if in addition to the manufacture of cigars there be a store for their sale, while if health were the object this floor, being the resort of more persons than the others, would certainly be under the provisions of the bill. The law fails to secure health to any reasonable extent, but in the words of the judges it accomplishes a very different thing: "If the act were general and aimed at all tenement-houses, and prohibited for sanitary reasons the manufacture of cigars and tobacco in all such buildings, or if it prohibited such manufacture in the living rooms of all tenants, another case would be presented. But in the form in which it comes before us it is so unjust in its inequalities, so harsh and oppressive upon the labor of poverty, so keenly discriminative in favor of the stronger classes engaged in the same occupation, that it certainly ought not to have been enacted."

It is said that the large manufacturers were confidently expecting that the constitutionality of the bill would be upheld, and have been perfecting machines which would do away very largely with hand labor. If these machines should really be set at work the result will be deplorable, as the workmen would be in the position of having the opportunity for work given them again but the work all taken away from them. The decision of the General Term may be appealed from, and if so the matter cannot be considered as settled.

The second case referred to was one in the New Jersey Court of Chancery, where an application was made by the Board of Health of Lambertville for an injunction preventing the proprietor of a tomato-canning establishment from turning the refuse from his works into a creek, it being alleged that the odor of the decaying vegetable matter was injurious to the public health. The case was bitterly contested, and, as is usual in such cases, the expert evidence presented was, much of it, absolutely contradictory. It was claimed on behalf of the defendant that the smells were not harmful, and also that others were responsible for the unhealthy condition of the town. The Vice-Chancellor, in deciding the case, held that the defendant's factory was the primary source of the nuisance, and that this made him responsible, even though the bad condition of the sewer and the discharges of filth by other persons might have contributed to the nuisance; and a decree was made forbidding any further deposit of the decaying vegetable matter.

There are a number of similar cases depending upon this decision, which is an important one as tending to strengthen the powers of boards of health.

ACUTE PAINFUL PARAPLEGIA.

UNDER the name of "acute painful paraplegia" M. Dumolard describes an affection which closely simulates an attack of rheumatism. The pains suffered by the patients are often intolerable, and the paralytic symptoms, which they rarely mention, may pass unperceived. The affection is then characterized by the following phenomena: paralytic symptoms feebly manifested, but with very intense pains; on this account Dumolard calls it "acute painful paraplegia."

This designation, however, is insufficient, as it says nothing of the seat and nature of the malady. It is characterized, at the beginning, by sharp pains in the regions of the kidneys and in the lower limbs, soon followed by incomplete paralysis of the abdominal members and of the bladder, with hyperexcitation of the reflex acts of the lumbar portion of the cord. In some cases the pains leave the lower limbs and attack the upper part of the trunk and the upper limbs, thus causing a very painful though incomplete cervical paralysis. Though lasting for a considerable time, the affection seems to tend always toward a cure; but its course is not always simple and regular.

As the disease is somewhat rare, and as nothing is known of its nature or anatomical situation of the pathological disturbances caused by it, it may be interesting to give a short *résumé* of the symptoms presented in the cases reported by Dr. Dumolard. The affection commences, as has already been stated, with acute pains in the kidneys and lower limbs. Both limbs are affected, and the pains extend to the feet. At times they are very severe, and are accompanied by muscular contractions and cramps of the thighs and legs. They sometimes come on without appreciable cause, while at other times they are produced by attempts at movement, by a shock, or even by a slight touch. The reflex power of the cord is evidently in a state of hyperexcitation. The patients seem to be fully aware that the pains are not the sole cause of the loss of the power of motion. The pains gradually increase, extend to the bladder, and micturition becomes painful. These cases were at first diagnosticated by Dumolard as rheumatism, for which he prescribed salicylate of soda, with the view that the meninges were affected, but without result. In a variable time, three to six weeks, the condition begins to improve, and the affection seems to pass off spontaneously. In other cases the pains begin in the shoulder and extend to the wrist. In these cases the bladder may not be affected.

We have now briefly analyzed the principal symptoms of this curious affection. It commences with a lumbar pain, with a sensation of weight in, and radiation into, the back. It may be at first very acute and then gradually diminish in intensity; at other times it is slight in the beginning, and becomes more and more violent. It first commences just below the kidneys, then attacks the dorsal region and ascends toward the neck. The pains in the legs do not always follow the course of the sciatic nerve, nor are they localized in the joints, as in articular rheumatism, but are seated, as a rule, along the entire surface of the affected limb. Whatever may be the manner in which the affection commences, the patient soon becomes completely paralyzed in the painful regions, while the pains still continue. The reflex power of the cord is then slightly exaggerated, and the least shock to the feet, or the least movement of the affected parts, is sufficient to cause the painful tetanic contractions. Is it not possible that this exaltation of spinal reflex may explain, in certain cases, the sort of muscular impotence which prevents movements on the part of the patient, rendering him incapable of taking a step, while in the horizontal position their muscles appear to be very strong? Will not this also explain the difficulty of micturition, by supposing that the exaggeration of the reflexes causes a contraction of the neck of the bladder?

The general state in this affection is never grave; the pulse rarely goes above 80; the skin is moist; the tongue, though white, remains moist, and the general aspect of the patient is indicative only of pain. The bladder is generally affected, and the patient makes futile attempts to completely evacuate it. The paralysis of the bladder and limbs is never complete, however. As a rule, the pains are confined to the region of the kidneys and to the lower limbs during the whole time; they may, however, as stated before, suddenly leave these regions and attack the arms and upper part of the body, and give rise to symptoms of painful and incomplete paralysis of the cervical region. The pains do not follow the nerve-trunks, nor are they localized in the vicinity of the trunks; the entire surface of the limb is affected. Nor are there any lancinating pains, such as are seen in cases of neuralgia.

The cause of the affection is obscure. All of the patients seen by Dumolard were in middle life and of the working class. Most of them referred their attack to exposure to cold or wet. It is noticeable that in six cases out of seven the patients were attacked in February or March. Furthermore, all of the patients were males. The treatment is necessarily symptomatic; energetic revulsants over the region of the cord should be used perseveringly; the saline purgatives are indicated for the saburral state of the digestive tract; bromide of potassium, as a moderator of the spinal reflexes, is also indicated. Chloral and morphine are indispensable for reducing the hyperæsthesia of the limbs and for the insomnia. It would seem that the electric current would be useful in the paralyzed condition of the limbs.

An affection almost precisely similar to this in every respect was described by Bockhammer some years ago, and an analysis of his paper may be found in the *Revue des Sciences Médicales*, vol. viii., p. 183. It appeared as an epidemic in Spain under the name of the Azannon disease, from the village where it appeared for the first time. The description of it given by Bockhammer corresponds in almost every detail with that of Dumolard.

Can it be that this is an abnormally mild form of spinal meningitis? Or may it not be due to lead-poison? It is scarcely probable that it is a manifestation of syphilis. Certainly its etiology is very obscure, nor is it likely to be cleared up, seeing that the patients all recover.

THE NEW PENAL CODE AND THE RHINELANDER CASE.

In our issue of September 20th we gave the main facts regarding the Rhinelander case, which for many reasons has excited unusual interest in the community. The defendant, Mr. William C. Rhinelander, committed a homicidal assault upon Mr. John Drake, whom he believed to be alienating the affections of his (Rhinelander's) wife. Being brought to trial, the prisoner's relations claimed that he was insane, while he himself denied this and contended that he should be brought to a criminal trial for his act.

The position thus taken by the prisoner was unique. But besides this, the trial involved the application for the first time of the sections in the new Code providing for

the trial of persons who put in a plea of insanity as an excuse for crime. The law says that if any person under indictment for the crime of murder or attempt at murder shall appear to be insane, the Court of Oyer and Terminer may, with the concurrence of the presiding judge, inquire into the sanity of such person, and may for that purpose appoint a commission to inquire into the facts of the case and report to the court. Such a commission was appointed by Recorder Smyth, which consisted of Dr. William Detmold, Mr. Patrick Nolan, and Mr. Edward Paterson. A large amount of evidence was taken. A report was finally made to the Court, in which two of the commissioners, Dr. Detmold and Mr. Nolan, stated the opinion that the prisoner was insane, while Mr. Paterson gave a contrary opinion.

Recorder Smyth has recently, after reviewing the evidence furnished by the commission, reversed its decision and decided that the defendant is sane. In doing this he establishes the precedent that a judge may reverse the decision of the commission he appoints. The case, besides furnishing a precedent on the above point, is instructive in that it shows how valueless expert testimony may still be, even under the new law. This law, in fact, though it gives some additional guarantee that the sanity of a prisoner is submitted to a careful test, does not in the least improve upon the mode of getting expert opinion. In the present case the weight of scientific opinion was almost entirely on the side of Rhinelander's insanity. In fact, we do not recall a single name among the experts put up by Rhinelander's counsel which would carry weight in the profession. As long as lawyers can set up any doctor, however unqualified as an expert, we must expect the present state of affairs to continue. It is as ridiculous to assume that every medical man, even if he has had a little special experience, is an expert on insanity as to suppose that every general practitioner is an ophthalmologist or a dermatologist.

DEAD TEETH IN THE JAWS.

It would be well if the dead (pulpless) teeth filled and left in the jaws of people were labelled "at the owner's risk," and all golden "crowns" and "bridge" structures attached to dead teeth marked "extra hazardous;" for it appears that when the pulp of a tooth has been removed life no longer exists in the dentine, which derives its nourishment from the pulp, and there is no way of preventing the dead matter left in its canaliculi from undergoing decay for an indefinite period of time. This matter has been touched on by our correspondent in another column, and we believe that the attention of the general practitioner is now being directed to this subject more than heretofore. It would seem that dentistry has perhaps been over-zealous in its efforts to retain defective teeth in the mouth, or to supplant them with apparatus which often proves to be anything else than harmless to the patient. In carrying both of these branches of dentistry to what the medical mind regards as a dangerous extreme, the health of the patient has too often been lost sight of. This, after all, naturally enough, was to be expected so long as medical men relegated the management of nearly all diseases of the mouth, such as the removal of dead teeth, the treatment of alveolar abscesses, diseases of the antrum of Highmore, and facial neuralgias, to dentists who possessed very little if any knowledge of medicine. It is in consequence of this course that the treatment of jaw diseases has been lost sight of by the general surgeon, and we fear that the well-intended efforts of dental schools to impart surgical knowledge to the mere mechanics who constitute by far the greater number of their students, will not remedy this neglected feature in medical education.

Dentists having a predilection for surgery of the jaws would do well to recognize this state of things, and to bear in mind that a medical education and training are necessary accomplishments to acquire before the study and treatment of any region of the body may be successfully taken up. In this way only may the aspirant establish himself in any medical specialty, so as to gain the confidence of the profession. At the present time it is believed that not over five per cent. of dental graduates, not to mention others who practise dentistry, have taken the degree of M.D., and of these a very small number have had any training in the practice of medicine.

The practitioner, in the meantime, who neglects to inquire into the state of his patient's teeth, may encounter much difficulty in overcoming diseases, especially those about the head, which can in any way be affected by reflex nervous influences from this source; and when the question of the removal of a dead tooth which gives rise to disturbance is considered, it should not be forgotten that local pain may be entirely unobserved by the patient.

News of the Week.

Dr. David B. Miller, of this city, died on November 1st, of Bright's disease. He was born in 1836, and graduated at the College of Physicians and Surgeons in 1858.

Dr. Paul Grawitz, of Berlin, assistant at the Pathological Institute, under Virchow, has been appointed to the charge of the Carnegie Laboratory, Bellevue Hospital Medical College. Dr. Grawitz has made a number of very scientific pathological researches, and is eminently qualified by training to fill successfully the position to which he is chosen. The faculty of the college are showing a desire to make the Carnegie Laboratory an institution of positive practical and scientific value not only to their students but to the profession of the city.

Our Medical Centenarian.—*Harper's Weekly* publishes an excellent portrait of Dr. Christopher Columbus Graham, of Louisville, Kentucky, who recently arrived at the age of one hundred years. His fellow-citizens celebrated the occasion by tendering him a banquet.

A Doctor's Heroism.—Under this title the *London Spectator* gives an account of a Dr. Samuel Rabbeth, of London, who sucked the diphtheritic membrane out of a trachea tube to prevent the suffocation of his patient. He caught the diphtheria himself and died.

Another French Cholera Commission.—Professor Jules Aronssohn has been appointed by the French Government as head of the commission to study the cholera in Italy.

The Latest Estimate of the Deaths from Cholera is as follows: France, 6,741; Corsica (estimated), 100; Algiers (estimated), 200; Italy, 12,283; Spain, 436. Grand total, 19,760. The above represents a period of from June 14, 1884, when the first case occurred at Toulon, to October 15th. There were probably about 50,000 cases of the disease.

Bequest to Indigent Medical Students.—The late Countess Bose, of Kassel, has left to the University of Berlin, 780,000 marks as a fund for the use of indigent medical students.

Professor Du Bois Reymond Challenged by a Quack.—*Ex gratia* Bismarck, Professor Schweininger has challenged Professor Du Bois Reymond to fight a duel, Schweininger having taken offence at the remarks of Reymond on his appointment to a chair in Berlin University. Professor Reymond declines to fight.

Two Decisions Regarding the Pay of Expert Witnesses.—Judge White, of Pennsylvania, has decided that under the law a physician must answer a summons from a court to appear and testify as an expert without remuneration.

A directly contrary opinion to Judge White's was recently delivered in the Circuit Court of Chicago. A dispensary patient sued Dr. Hotz and his substitute, Dr. Lee, for the loss of an eye, claiming $10,000. Another physician was summoned to testify as to facts in the case. Being then asked to testify as an expert and give an opinion, he refused.

"This action of the court," says the *Weekly Review*, "is of considerable importance, as it shows that a physician cannot be made liable for any act of his *locum tenens* when duly qualified by law, and further that no physician is obliged when subpœnaed as a witness of fact to express an opinion as an expert."

The Oldest Living Microcephalic.—At a recent sitting of the Berlin Medical Society, Professor Virchow exhibited a girl, aged fourteen, with a slight though normally developed figure, but with a diminutive head, scarcely as large as a man's fist. She came from Offenbach, and was introduced by her mother, a tall, large-boned woman. Her face is not larger than that of a new-born child, with a sharply projecting nose and prominent jaws; her complexion is delicate, and her features resemble those of a bird of prey. The size of the brain in this diminutive skull is proportionately small, and the intellectual powers are not developed beyond those of a six-months child. The only word, besides some inarticulate sounds, that the girl can pronounce is mamma. The parents had had seven children, of whom four were microcephalic, but only the one exhibited had lived. When she was at home she sat quietly, and preferred avoiding the society of other children, generally withdrawing into a corner of the room. She ate and drank purely mechanically. Virchow referred to this case as the oldest one living. At the recent meeting of the French Association for the Advancement of Science, Dr. Magitôt reported the case of a microcephalic woman, aged thirty, weight seventy pounds. She showed more intelligence than Virchow's case, and could dress, take care of herself, and speak several words.

The Board of Health of this city receives this year an appropriation of $420,282. It wanted $17,000 more.

American Use of the Thermometer in Disease in 1808.—In Dr. Elisha North's "Treatise on Malignant Epidemic Spotted Fever, or Cerebro-Spinal Fever," he tells us, page 41, that it will always be well to ascertain the degree of the patient's heat by a thermometer.

Medical Department University of Vermont.—Dr. W. Oliver Moore has been appointed Professor of Diseases of Eye and Ear, in place of Dr. D. B. St. John Roosa, who has resigned, and Dr. Stephen S. Burt has accepted the chair of Professor of Physical Diagnosis.

Pacini's "Cholera Germ."—It has been stated that Professor Pacini, of Naples, announced the discovery of a cholera-microbe as early as 1855. A claim of priority over Koch has been put in, to which, however, we at the time denied validity. Dr. A. Bianchi, of Florence, has just collected and published Pacini's works upon this subject, from which it appears, as we anticipated, that the particular microbe found by the Italian professor differs entirely from that of Koch. It is a vibrio found in the intestine, and which by its growth produces irritation.

M. Ricord on the Cholera.—At a recent meeting of the Paris Académie de Médecine the venerable Ricord made some remarks upon the cholera. He believed that it was not contagious, and that it originated *de novo*, and was not always imported. Ricord's experience was during the epidemic of 1832. His views are in accord with those of Jules Guérin.

Statistics of Cholera in Italy.—Considering the brevity of its duration, according to *La Gazzetta degli Ospitali* (*Lancet*), the present epidemic of cholera in Naples has exceeded in severity all previous invasions, including the terrible one of 1837. That was the cause of 13,800 deaths in five months. The first death from cholera in Naples this year occurred on August 21st. From that day to midnight, September 30th, the cases numbered 10,957, and 5,778 deaths. In the hospitals the recoveries were 1,121, the deaths 787. The actual population of Naples is 500,000. At Torre Annunziata 137 deaths occurred in 234 cases. From the 1st to the 30th of September 294 soldiers of the Naples garrison were attacked with cholera, 134 of them fatally. The mean mortality was 42 per cent. In the aristocratic quarter of Chiaja, during the whole of September, 162 deaths occurred among 252 cases of cholera. By far the greatest number of victims were women.

Death from Cholera of a Distinguished Italian Physician.—We chronicle with regret the news of the death of Professor Luigi Somma, of Naples, the founder and director of the recently established periodical devoted to the study of diseases of children, and entitled *Archivio di Patologia Infantile*. A victim to cholera, the scourge which has so devastated the beautiful city in which he lived and labored, he fell at the post of duty and of honor, on September 19th last.

Another Doctor's Novel.—A well-known London physician has just published a novel called "Gaythorne Hall." It is well spoken of.

Klein's "Bacillus Dinner."—The report that Dr. E. Klein swallowed a dose of cholera bacilli is laughed at in Berlin circles among the supporters of Koch. It was a sensational performance, they assert, and proves nothing, except that a suitable nidus is necessary for the bacilli to develop in—which Klein did not have.

Dr. James C. Carson of the Institution for the Deaf and Dumb in this city has, says the New York *Medical Journal*, been appointed Superintendent of the State Idiot Asylum at Syracuse.

Two Faculties and One College.—The style of two medical colleges and one faculty is not new, and used to be served up at Louisville, Ky., with considerable financial success. To have two faculties and one college, however, is rather novel. Says the *Maryland Medical Journal:* "The dissensions between the two factions claiming to be the Baltimore Medical College have been freely ventilated by the secular press of this city. The state of the controversy has not changed, and the claims to the right of title and property of the college will have to be decided by the courts. Two Faculties, having separate buildings, are instructing students under the charter of the Baltimore Medical College. This is a unique controversy, and its results will be watched with interest. So far as we can judge, the Monroe faction seems to have the advantage up to the present time."

The Charity Organization Society and the Medical Charities.—The Second Annual Report of the New York Charity Organization Society states that it now has one hundred and eighty-three charitable societies co-operating with it. Among these there are only seven medical charities, viz.: Home for Convalescents, House of Rest for Consumptives, New York Hospital, New York Infirmary for Women and Children, Northern Dispensary, Woman's Hospital, Columbian Institute. It is evident that as yet there is very little medical "charity organization" despite all that has been said.

The Courage of Physicians.—*The British Medical Journal*, under date of September 17th, states that three professors and five physicians had been attacked with cholera during the discharge of their duties at Naples.

The *Medical and Surgical Reporter* gives currency to a statement that a young Pole, living in Warsaw, has offered himself in the interest of science to be experimented upon in reference to the cholera. "I am unmarried," he says, "I have no ties of any kind, and no plans for the future." His offer had better be taken.

The Peculiar Progress of the Italian Cholera Epidemic.—A *Lancet* correspondent writes that there are certain phenomena peculiar to this outbreak of cholera in Southern Europe which should form the theme of careful official inquiry. After the outburst of the malady in Toulon its direction was much less northward than southward. Again, both in Italy and France it visited great seaports most heavily, while in Italy this curious spectacle was witnessed—it selected alternate seaports for attack. For example, it overleaped the populous and not over-cleanly Genoa, and alighted heavily on the less populous and not more insanitary Spezia. Again, it overleaped the less populous and decidedly insanitary Leghorn, and exploded with fearful violence in the more populous, though not very much more insanitary, Naples. What was its principle of selection? How is it that Messina and Palermo, seaports so severely scourged by it in former visitations, escaped so cheaply on this occasion? And how is it that the great provincial capitals—Turin, Milan, Venice, Florence, and Rome herself, all of them the scenes of virulent outbreaks on previous occasions—have hardly had one case?

Cholera and Cleanliness in Naples.—A correspondent of *The Lancet* writes that the mode in which the cholera attacked the people of Naples has been very perplexing to the hygienists. For example, the narrow, ill-ventilated streets intersecting blocks of buildings in which the population teems like rabbits have been precisely those in which cholera has numbered least victims; while the dwellings which, from their amplitude and situation, the freely aired thoroughfares dividing them, are in marked contrast to the preceding, have contributed the heaviest contingent to the hospital and the cemetery. Again, the ill-fed, badly clothed, unwashed inmates of the rookeries have come off very lightly in comparison with the well-dieted, comfortably clothed, not uncleanly bourgeoisie. "Partly because by nature," says the correspondent of the *Opinione*, whose letters from Naples have given the best account of the epidemic, "we have something of the Arab, partly because the facts above stated reinforce the sentiment of fatalism which is at the bottom of our southern character, our populace laughs to scorn all the admonitions of the authorities and devours figs, capsicums, tomatoes, more or less unripe, does everything in fact which it has means to indulge in, though forbidden by the profession. As to soup-kitchens, it will have none of them. 'They,' it says, 'are for the sick, and we are quite well.'" All this, however, should not shake our faith in the efficacy of pure water and cleanly dwellings.

A Floating Hospital.—Chicago has followed the example of New York, and last summer established a floating hospital, upon which twenty-one thousand four hundred and eighty-nine persons were cared for and treated.

A Novel Introductory.—The custom of giving formal introductory addresses is growing less popular in England, owing, it is said, to the too boisterous way in which they are received by the students. The opening ceremony in connection with the London Medical School this year took an unusual form, which possessed the merits of originality, interest, and usefulness. The customary presentation of prizes was made, and short addresses were delivered. On the conclusion of these formal proceedings, the field at the back of the hospital became the scene of further operations, and being limelighted, was seen to be transformed into a battle-field strewn with the dead and dying remnants of a defeated army. To these entered an ambulance corps, the members of which immediately set about the stern business of caring for the injured militants; and realism was still further obtained by the introduction of a number of ladies in the red cross uniform.

Reviews and Notices.

Hooper's Physician's Vade Mecum: A Manual of the Principles and Practice of Physic; with an Outline of General Pathology, Therapeutics, and Hygiene. Tenth Edition. Revised by William Augustus Guy, M.B. Cantab., F.R.S., Fellow of the Royal College of Physicians; Late Professor of Forensic Medicine and Hygiene, King's College, London; Consulting Physician to King's College Hospital, etc., etc., and John Harley, M.D. Lond., F.L.S., Fellow of the Royal College of Physicians; Honorary Fellow of King's College, and Late Physician to the London Fever Hospital; Lecturer on General Anatomy and Physiology at, and Physician to St. Thomas' Hospital. Volume II. New York: William Wood & Co. 1884.

The second volume of Hooper's Manual appears as the monthly number of Wood's Library, following immediately in order the first volume. It contains the greater portion of the practical part of the work, the first volume having been devoted chiefly to an outline of general pathology, therapeutics, and hygiene. At the end of the book there are tables of remedies and formulæ, a glossarial index, and a general index. As to the value of this work, we can only repeat what was said in noticing the first volume. It is one of the best manuals of practical medicine in existence, complete enough to serve as a guide in the treatment of disease, and yet so compact as to allow of ready reference by the practitioner, to whom time is of value.

Corpulence and its Treatment on Physiological Principles. By Dr. Wilhelm Ebstein. Translated from the Sixth German Edition by Prof. A. H. Keane. Wiesbaden: J. F. Bergmann. New York: B. Westermann & Co. 1884.

We have already reviewed a so-called "popular" edition of this book. We have nothing to add concerning it now, except to recommend it as a most suggestive and useful monograph. The present edition is complete and is well printed.

The Principles of Ventilation and Heating and their Practical Application. By John S. Billings, M.D., LL.D. Pp. 214. New York: The Sanitary Engineer. 1884.

Originally written as a series of papers contributed to the *Sanitary Engineer*, the material composing this work has been rearranged and amplified into a quite complete and most readable book. The author has entered into his task with an evident desire to supply to the medical profession, as well as to the interested in sanitary matters in general, much-needed information on a highly important subject, and to do so in a manner both rational and practical. In this rather difficult undertaking he has succeeded most admirably. He first shows the impossibility of accomplishing anything in the way of ventilation without some knowledge, at least, of the principles of physics as affecting the relations of gases; then explains these principles as briefly and clearly as could be desired; and finally details their application to private dwellings, churches, theatres, and hospitals. He maintains, as is self-evident, the intimate connection between heating and air-supply, and shows the absurdity of attending only to the one to the neglect of the other. He then considers the different methods of heating, as applied to the various kinds of buildings, always with a view to securing the necessary and proper purity of the air. The text is elucidated by drawings, particularly of plans of some of the more recent and improved structures, explaining their merits and defects. In short, the book is one that every physician should make himself familiar with. The questions of hygiene, with a view to preventive medicine, are constantly assuming greater importance; and among them that of sanitary warming and ventilation is by no means of secondary importance, and one with which the medical man must familiarize himself. Dr. Billings' book will tell him just what he wants to know. The author is one of a class of whom we have unfortunately too few in this country; men who are in a position and who have the ability and inclination to apply themselves to the scientific studies of the profession, without having constantly in their minds the question whether the result can be utilized in their practice so as to bring in returns in dollars and cents. This contributes in no small degree to that judicial fairness of mind which is requisite in writing to instruct; and as a result this book of Dr. Billings is noticeably free from bias or prejudice, while the clear and forcible style makes the work interesting as well as instructive. Considering the value of the book, it was deserving of better treatment at the hands of the publishers; the type, though clear, is small and very trying to the eyes. If the book had comprised another hundred pages, the increase in price would have been more than compensated for by the ease in reading.

A Treatise on Physiology and Hygiene for Educational Institutions and General Readers. By Joseph C. Hutchison, M.D., LL.D., ex-President of New York Pathological Society, etc. New York: Clark & Maynard. 1884.

In the revised edition of this admirable little work, considerable material has been added on the influence of alcohol and narcotics on health. Both of these are treated in a common sense manner. Some alterations are made throughout the text, which help to enhance the value of the book for beginners.

Manual of Chemistry: A Guide to Lectures and Laboratory Work for Beginners in Chemistry; A Textbook specially Adapted for Students of Pharmacy and Medicine. By W. Simon, Ph.D., M.D., Professor of Chemistry and Toxicology in the College of Physicians and Surgeons, Baltimore, Md. 8vo, pp. 411. Philadelphia: H. C. Lea's Son & Co. 1884.

This is a book for careful study rather than for the casual reading, either of the beginner or the advanced student. The mastery of its various lessons means work from beginning to end. It is impossible for any author of a treatise on chemistry to give his subject the attractiveness of a novel, and Professor Simon in this instance has certainly made no such attempt. He does his duty when he presents his subjects in all their nakedness of fact and sternness of chemical logic. This is done from beginning to end in an almost painfully terse manner. The work is divided into seven principal parts, which are naturally and simply arranged. The discussion of the fundamental properties of matter prepares the student for a proper appreciation of general chemical phenomena, next follows the consideration of the principles of chemistry, of the non-metallic and metallic elements, the old classification being in the main adhered to; next comes qualitative analysis, organic chemistry, and physiological chemistry. It will thus be seen that the general subject of the book is quite thoroughly treated, giving the student a comprehensive view, and preparing him for most thorough work in his department. It contains many beautifully colored plates of chemical reactions, which are in some instances made with the actual substance when possessing stability of color, and in others most artistically and beautifully tinted by the talented wife of the author.

Inula Campana in the Treatment of Leucorrhœa.—Dr Chéron mentions several substances which he states exert a beneficial influence in leucorrhœa. Among these the most efficacious, he thinks, is elecampane. It is given in infusion, tincture, extract, or powder of the root. The best preparation is an infusion of three drachms of the root in five ounces of boiling water, the whole to be taken in the morning.—*Rivista Clinica*, No. 8, 1884.

Correspondence.

"DEAD TEETH IN THE JAWS."

To the Editor of The Medical Record.

Sir: It appears that the allusions to "pain in the ears due to irritation in the jaws," etc., under "Hospital Reports," and my comments thereon in The Record of October 4th, have called forth dissenting views in the two subsequent issues.

Lest silence might be construed as yielding assent to your correspondents' views, I would beg space to reply briefly to some of their strictures. Before so doing, however, it might be well to state that the cases reported by my senior assistant, Dr. Bartlett, as coming to the ear clinic, were not intended to specially illustrate dental affections; but it was believed that such examples of reflected dental irritation would not be devoid of interest to the profession. The extraction and filling of the teeth, where required, it may be said, is intrusted to our own dentists, who are competent to do such work.

In regard to the exceptions taken to the concluding paragraph of the report, I cannot think that, from a clinical point of view, the statements were either too sweeping or overdrawn. Thus the retention in the jaws of teeth which are diseased from death of the pulp or from caries have become irremediably sensitive to thermal influences, or have been deprived of adequate periosteal nourishment through calcareous formations about the roots, very frequently gives rise to nervous diseases about the head. I am convinced that these reflected nerve influences manifest themselves much oftener since dentistry has come more extensively into practice during the present generation, and greater efforts are made to retain defective teeth in the jaws; and, moreover, the very general introduction of apparatus for retention in the mouth of substitutes for absent teeth is apparently accomplishing much harm also. Nor does the energy displayed in increasing this industry not give promise of speedy reform. I am not sure that the injurious results alluded to are always due to the work of less informed operators, as has been alleged, since it has been my lot to have frequently seen morbid processes kept up in the ears for a long time by diseased teeth which dentists of repute were "treating," and speedy recovery has followed the tooth's removal. Indeed, while writing this letter a well-known medical man who practises dentistry in this city came to consult me about an inflammation of one of his ears, which began to trouble him from the time the upper second molar of that side was "treated" for a diseased pulp, and he himself is convinced that the offending tooth lies at the bottom of the difficulty.

The gist of the whole matter, however, seems to lie in the question, *Whether it is safe practice to retain dead teeth in the jaws.* Teeth seem unlike other parts of the osseous framework, inasmuch as they are developed from without, so to speak, and are afterward left constantly exposed to atmospheric, chemical, and mechanical influences liable to set up destructive processes in this substance. When limited caries results, its progress may be interfered with for a longer or shorter period of time by stopping the cavity, but when the nutrition of so large an area of the bone is interfered with, as occurs from death of the pulp, it would seem that in a large number of instances irritation cannot be so easily controlled, and the affected tooth becomes more or less of a foreign body, since the moment the pulp dies, thus *cutting off the source of nutrition from the dentine*, the part thus nourished must of necessity die also. In fact the tooth, having a vascular or nervous supply from both periosteum and pulp, the impairment of either must affect it.

From a review of this subject we were further led to believe that in the case of no dead (pulpless) tooth, however carefully treated and filled, can it ever be successfully demonstrated that a slight irritation is not constantly present, although no appreciable irritation may be experienced by the patient.

In regard to the treatment of pulpless teeth, the practice in vogue seems the reverse of procedures founded on well-established surgical principles, since stopping the natural outlet for the escape of putrescent products from portions of the pulp left remaining in the canal and in the dental canaliculi through the exterior part of the tooth itself, makes their passage into the tissues underneath unavoidable. This diversion of the drainage must be of questionable propriety in many instances, since the tissues about the roots of dead teeth are liable to become infiltrated with the products of decomposition, the absorption of which, when slowly formed, is much more liable to contaminate the system than the discharge of pus into the mouth from an alveolar abscess. Furthermore, inflammation of exposed dentine cannot surely be entirely arrested in any case by filling the pulp-cavity with any known extraneous material, and especially is handicraft wanting to even imperfectly protect the minute and often tortuous canals leading down to the apical foramina of the majority of the teeth. The most skilful operator can, under these circumstances, at best but hope that his work will not soon be followed by trouble arising from the escape of deleterious matter into the tissues about the root, or the development of pericementitis. He is able only to offer a hopeful but uncertain prognosis in these cases, but the patient may all the same remain an unconscious sufferer in respect to the slow but persistent irritation of the surrounding tissue; the irritation thus propagated from the dead tissues of the dentine will sooner or later most likely be transmitted through the tissue of the cementum to the periosteum. It is true that through the periosteum alone the dentine may long derive some nourishment, yet in the meantime periostitis often exists, so that the patient, without having actual pain, is always conscious of undue tenderness about the root of the dead tooth, which may be much exacerbated by a severe cold or any sudden wrenching of the tooth, as in biting some hard substance. A person with a pulpless tooth in his jaw which has been stopped, cannot even consider himself free from the danger of reflected irritation and its various consequences, and he may, moreover, at any moment experience more or less inflammation about its roots.

That a defective tooth in many instances may remain in the jaws of a healthy person for an almost indefinite period without doing appreciable harm, surely does not warrant the risk being taken in a very large number of cases, since what may be tolerated quite well in the strong and robust will set up serious trouble in those who are run down from any cause, in subjects of catarrhal affections, and the like; in these the more an offending tooth is "treated," the worse in many cases it will be for the patient. The writer has been much impressed by witnessing the sufferings endured by weak and nervous persons during ineffectual attempts to "treat" and "cure" their pulpless teeth, and he cannot but regard such practice as questionable. Indeed, his experience in practice leads him to believe that some diseases cannot be successfully treated so long as dental irritation is maintained.

It is in respect to matters of this kind that a medical opinion is often much needed. The question of the usefulness of retained dead teeth in certain cases is of such importance that persons are willing to assume more or less risk to health rather than be deprived of a useful grinder or an ornamental incisor—these are questions which no discussion can ever settle.

Samuel Sexton, M.D.

12 West Thirty-fifth Street, New York, October 28, 1884.

An American Physician to Deliver the Gulstonian Lectures.—Prof. Wm. Osler, of Philadelphia, will deliver the Gulstonian Lectures at the College of Physicians, in London, in 1885.

PROFESSOR ALFRED L. LOOMIS ON COLORADO CLIMATE.

To the Editor of The Medical Record.

Sir: Of the recent medical publications there is perhaps none that is receiving more general attention from the profession than Professor Alfred L. Loomis's "Practical Medicine," and there is probably no portion of this work which will be more eagerly read, or which will carry more weight, than that which has reference to pulmonary troubles, and especially to the climatic cure of phthisis. The wide-spread reputation of the author as a diagnostician in these troubles, and his well-known experience, will give, in the mind of the general reader, the weight of authority to whatever he may say on these points.

That Professor Loomis places great stress on the element of climate in the cure of phthisis is seen by his assertion that "each year's experience impresses on me the conviction that while climate, more than any other agent, has a controlling influence over phthisical developments, each case must be carefully analyzed before any definite directions can be given as to the climate best suited to it."

To the medical profession of the Rocky Mountain region this question is of such vital interest that our first point of investigation, on receiving the "Practical Medicine," was to see what Professor Loomis had to say about our climate. Our curiosity was whetted the more because of our remembrance that, in his treatise on the "Diseases of the Respiratory Organs, Heart, and Kidneys," page 281, he has committed himself to the opinion that "the climate of Colorado is mild and peculiarly dry, from its elevation; the atmosphere is highly exhilarating and peculiarly healthful. Here flowers grow at the height of eight thousand feet; usually at a much less height vegetation does not flourish. The rainfall for one year was about sixteen inches. *In some sections there are but slight variations of temperature throughout the year. The winter days are those of a northern summer, and the summer is but little warmer than winter.*" (The italics are mine.)

What was our surprise, then, to read in his "Practical Medicine," page 205, that "there is one grave objection to Colorado as a winter refuge—the enormous monthly and also diurnal range of temperature must severely try any invalid. During March, 1880, the thermal range at Denver was eighty-three degrees, and in December, 1876, it amounted to ninety-three degrees; a change in a single month greater than occurs at London in a whole year, and greater than occurs at New York in a whole winter."

Certainly there is a wide variance between these two opinions, and as it is not to be presumed that the character of the Colorado climate has been changed to such a degree, in a few years, as these two quotations would lead one to suppose, the reader can simply conclude that Professor Loomis's personal experience of our Colorado climate has led him to change his views, and that he no longer holds that our "winter days are those of a northern summer."

The writer is, however, somewhat doubtful whether this would be a correct conclusion, and he thinks it more probable that Professor Loomis has been misled by others in his opinion expressed in the "Practical Medicine." My reason for thinking so is, that in looking over the files of the *New York Herald*, under date of December 29, 1883, in an editorial entitled "Winter Resorts for Invalids," beginning: "Dr. S. A. Fisk, writing from Denver, recently published in *Science* an interesting paper containing the results of an extensive investigation of the relative merits of different American sanitaria in the cure of consumptives," I find the following: "But there is one apparently grave objection to Colorado as a winter refuge, which Dr. Fisk seems to estimate too lightly. The enormous monthly and also diurnal range of temperature must severely try any invalid. During March, 1880, the thermal range at Denver was 83 degrees, and in December, 1876, it amounted to 93 degrees—a change in a single month greater than occurs at London in a whole year, and greater than occurs at New York in a whole winter."

Further on in the "Practical Medicine," pages 206 and 207, is the following, viz.: "Recently *Davos am Platz*, in the Swiss Alps, has been most extensively visited. Williams, Albutt, and other English physicians give very favorable reports of it. It is 5,200 feet above the sea, very dry, but not windy, and not changeable. Davos possesses also the unique climatic characteristic of freedom from high winds (the records showing that from October 1, 1880, to March 31, 1881, there were one hundred and thirty-four days with 'no wind'), while its 'sun temperature' rises even in January, as Dr. Franklin notes, as high as 150°—conditions which admit of much invaluable out-door exercise by invalids. Doubtless some high winter resort combining these vitalizing conditions can be found in the Southwestern Rocky Mountain region of our own country."

From the editorial already cited I quote the following: "Davos possesses also the unique climatic characteristic of freedom from high winds (the records showing that from October 1, 1880, to March 31, 1881, there were one hundred and thirty-four days of 'no wind'), while its 'sun temperature' rises even in January, as Dr. Franklin notes, as high as 150°—conditions which admit of much invaluable our-door exercise by invalids. Doubtless some high winter resort combining these vitalizing conditions can be found, as Dr. Fisk suggests, in the Southwestern Rocky Mountains."

These quotations seem to me to justify the conclusion that in speaking of the Colorado climate, Professor Loomis has drawn from the statements of others rather than given the results of his own experience.

To be sure, he may have been responsible for the editorial from which I have quoted, but a comparison of the two following passages makes me think that this cannot be.

In the "Practical Medicine," page 206, he says: "The extraordinarily dry belt of country which runs northward from San Antonio, Texas, has begun to endanger the supremacy of Florida as a health resort for the consumptive. That this belt offers some climatic advantages for weak lungs over the mild but rather humid air of Florida cannot be doubted."

In the editorial cited is the following: "Another writer in the *Philadelphia Medical Times* has also recently called attention to the virtues of our western climate in the treatment of consumption, and expresses the opinion that 'the extraordinarily dry belt of country which runs northward from San Antonio, Texas, has begun to endanger the supremacy of Florida as a winter health resort for the consumptive.' That this belt offers some climatic advantages for weak lungs over the mild but rather humid air of Florida cannot be doubted."

I should like to call attention to the fact that Professor Loomis speaks of the air of Florida as being "rather humid," and yet a little earlier, on the same page of his "Practical Medicine," he publishes the following: "Minnesota has a dry, cool, exhilarating climate. Southern California, Georgia, and South Carolina have a dry, warm atmosphere."

Now the records of the Signal Service Bureau, U. S. Army, accessible to anyone, show that the mean relative humidity, for a series of four years, was from 65° to 69° of saturation for Minnesota, Southern California, South Carolina, and Georgia. We give the data, viz.: Augusta, Ga., 69.2; Jacksonville, Fla., 69°; St. Paul, Minn., 67.3; Los Angeles, Cal., 65.8°; Denver, Col., 45.8°. These figures, together with the maps published by the Signal Service Bureau, at the earnest solicitation of the Colorado State Medical Society, prove conclusively that if the air of Florida is "*rather humid*," that of Southern California, Georgia, and South Carolina cannot be called

"*dry*"—certainly not in comparison with the dry air of the Rocky Mountain region.

In conclusion, the writer wishes to state that the two instances of the extreme range of temperature, cited by the editorial writer and also by Professor Loomis, are correct, and are taken from the records of the Signal Service; yet it seems to him that the citation of such unusual ranges is calculated to give an erroneous impression of our climate, for, as a rule, our winter days are warm and pleasant, so that it is not uncommon for persons to sit with doors and windows open, or to have picnics in the open air, even in the heart of January. The illustrations cited may do very serious injury to a climate whose beneficial effects "are incontestibly proved by hundreds of cases," and they may, especially when given the weight of Professor Loomis's authority, deter invalids from coming to a place of which so impartial a writer as Dr. Edward T. Ely has remarked: "Colorado can easily rest on its own merits. . . . Despite all objections which may be raised, the climate is probably, as we have already said, the very best of its kind at present available for invalids, and destined to grow in popularity as its merits become more accurately understood."

SAMUEL AUG. FISK, M.D.

373 CURTIS STREET, DENVER, COL.

BRIEF NOTE ON THE TREATMENT OF FRACTURE OF THE CLAVICLE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Fracture of the clavicle is one of those ailments which are not so serious as troublesome, from the difficulty of keeping the fractured ends in apposition. All the various apparatus for that purpose have failed, and the consequence of failure is a protuberance on the point of fracture, persisting through life, unsightly if not inconvenient.

To avoid this result I propose the following plan of treatment: Turn the arm of the affected side behind the back, and bring it as far backward as possible in such manner that the dorsal side of the hand comes to lie on the opposite buttock. To retain this position it is necessary only to fix a narrow strip of adhesive plaster around the wrist and thence around the body, or the whole arm may be fixed on the body by means of a roller bandage from under the axilla down to the crista iliæ.

I have adopted this plan for the last two years, treating in that way about a dozen cases (with one exception, all children), and the result in every case was a speedy union without deformity. The only drawback is the difficulty of lying down, and in fact in my first case, a girl of ten, the patient sat up in a chair day and night for two weeks, but I found after a while that the children are able to obtain perfect rest sleeping on the sound side.

S. TELLER, M.D.

306 WEST THIRTY-THIRD STREET, NEW YORK.

"THE HEMORRHOID QUACK."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: *A propos* of the communication which you published in a recent issue from Dr. Stevens, of Chillicothe, Mo., and in view of the fact that all parts of the country are infested by a class of illiterate, incompetent, and unauthorized "doctors" who advertise to "cure piles without pain," etc., I desire to report the following case which has very recently fallen under my notice.

General ——, a retired army officer, has long been a friend and occasional patient, his general health being much impaired from chronic cystitis and gastro-intestinal catarrh. He is a monomaniac on the subject of quacks and their remedies, and I suppose he has dosed himself with about every "safe" and sure cure ever concocted. The literature of suburban rocks and fences is to him a gospel, and the testimonials of eminent judges and divines are revelations.

Several days since I was summoned in haste to see the General. On arriving I found him in great pain, which he referred to the rectum, and explained by saying that he had been operated upon for piles, a few days previously, by a "doctor" whose advertisement he had read, and who had exhibited a number of very flattering testimonials from officers of the army and navy. Upon examination I found a sloughing ulcer upon the site of what had evidently been an external hemorrhoid. The bowels, too, he said, were acting very frequently, and seemed to be beyond voluntary control. Packing the sore with iodoform, and prescribing three drops of laudanum to be taken every two hours, with the object to heal the wound, control the pain, and restrain the bowels, I withdrew.

The wound progressed well, but in spite of opium, both by the mouth and rectum, frequent semi-involuntary alvine evacuations occurred. Three days after I first saw him he had a sudden and enormous discharge of clotted and fluid blood mingled with fecal matter. The odor was horrible. I now gave injections of ergot and hamamelis, and ordered opium suppositories to be continued. For forty-eight hours all went well, when there was another copious discharge of very offensive matter, consisting of blood, feces, and pieces of dark-colored membranous shreds and flakes. The patient was in a state verging upon collapse, and complained greatly of pain and pressure in the rectum. The pulse was weak and intermittent; surface cool and bleached, and countenance pinched. Vomiting came on, and things began to look serious. Examining the anus I saw a dark and putrid substance protruding, and, drawing upon it, succeeded in extracting about three inches of what proved to be a portion of the mucous membrane of the rectum. I was prevented from delivering the entire mass by attachments at the anal margin, and had to detach with scissors. Learning now that the quack had used some sort of injection, which I concluded was carbolic acid, and that he had either injected a number of hemorrhoidal tumors, or had ignorantly allowed a quantity of the solution to enter the bowel, I saw that I had to deal with a case of inflammatory sloughing of the lining membrane of the rectum. Digital exploration revealed roughness and great tenderness, and ocular inspection with a speculum showed an extensively denuded surface, congested and bleeding. Seeking to control any further hemorrhage and evacuative efforts, I now cleared away all débris, and, through the speculum, packed the bowel tightly with absorbent cotton soaked in a strong solution of glycerine and tannin, and afterward inserted a suppository containing two grains of opium. This treatment, I am happy to say, proved effective, and I believe my indiscreet friend is out of danger.

Well, here is an instance where an intelligent man places himself under the care of an impudent pretender for a disease which we all treat with the greatest caution, and always with anxiety; and he almost pays the penalty with his life. This pile-driver insisted on our friend taking his usual exercise, and did not even consider it necessary to see him again after the operation. But what are we to do about it? The public are free to consult whom they choose, and the religious press continues to spread the glad tidings of the miraculous performances of any and every impostor who will *pay* their regular price.

Unfortunately such results as here narrated are not generally circulated. Very respectfully,

GEO. B. FOWLER, M.D.

11 WEST FORTY-FIFTH STREET, NEW YORK.

THE PREVALENCE OF CONSUMPTION AT DIFFERENT AGES OF LIFE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: It may be of interest, in relation to the communications of Drs. Holden and Baker, in THE RECORD of July 12th and August 30th, relative to the above subject, which having been absent I have but just observed, to

present some results and conclusions found by myself in 1860. They are embodied in a paper, afterward published, read by me before the American Geographical and Statistical Society. Up to that time these statistics relative to the mortality from consumption under various conditions of climate, age, sex, etc., were the most extensive that had appeared, one table comprising 27,771,728 deaths from all diseases occurring in various parts of the world between 1804 and 1860. In this paper I have given three tables illustrative of its prevalence at various ages, the first from Boudin ("Géographie et Statistiques Médicales"); the second, constructed by myself, of 88,427 deaths from consumption occurring in various cities and countries; and the third, constructed by me from the Registrar-General's reports of deaths in England from 1848 to 1852, in 1856, and in London in 1857.

The table of M. Boudin relates to the deaths from consumption in England and Wales in 1847. It shows that of 53,317 deaths there occurred—

Under the age of 5 years							9	per cent.
Between 5	and	10	years				3.1	"
" 10	"	20	"				7.5	"
" 20	"	30	"				14.7	"
" 30	"	40	"				26.4	"
" 40	"	50	"				12.8	"
" 50	"	60	"				7.9	"
" 60	"	70	"				4.6	"
" 70	"	80	"				1.3	"
" 80	"	90	"				0.14	"
Above		90	"				0.035	"

The second table shows that of the 88,427 who died from consumption—

25.5	per cent.	died	between	the	ages	of	20	and	30;
20.5	"	"	"	"	"	"	30	"	40;
12.5	"	"	"	"	"	"	10	"	20;
12.3	"	"	"	"	"	"	40	"	50;
11 3	"	"	"	birth	and	10	years	of	age;
7.7	"	"	"	the	ages	of	50	and	60;
6.4	"	"	"	"	"	"	60	"	70;
1.3	"	"	"	"	"	"	70	"	80.

It has been variously stated by writers (I quote from my paper) that consumption is developed at an earlier age among females than among males. The following table shows this is not true before the tenth year, yet between that time and the forty-fifth year the various decades furnish a greater percentage of deaths among the females than the males; but that after the forty-fifth year the percentage is greater among the males.

Third table, of 409,862 deaths occurring in England and in London:

						Males.		Females.	
Under 5 years of age						8.4	per cent.	6.9	per cent.
Between 5	and	15	years			6.2	"	7.8	"
" 15	"	25	"			22.92	"	26.1	"
" 25	"	35	"			22.6	"	24.9	"
" 35	"	45	"			16.9	"	17.0	"
" 45	"	55	"			11.9	"	9.5	"
" 55	"	65	"			0.7	"	5.2	"
" 65	"	75	"			0.3	"	2.2	"
" 75	"	85	"			0.02	"	0.03	"

To save space, I have not given in the above tables the full figures, that is, the number of deaths at each epoch, but have simply calculated the percentages.

Though I recognize the cogency of Dr. Holden's statement, that, in order to show the age at which death from consumption is most liable to occur, the proportion of the deaths to the number of the living should be considered, and that a large proportion of deaths from it at ages when there are the greatest number living, does not show that it is most liable to occur at those ages; still, the above tables, I think, are of equal value in showing, without regard to the living, the periods when death from the disease is most liable to occur.

Yours truly,

H. B. MILLARD, M.D.

NEW YORK, October 20, 1884.

A PHYSICIAN'S EXPERIENCE IN HIS OWN FAMILY IN CHILDBIRTH AND INFANT FEEDING.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Your readers will all recall the discussion of puerperal fever in THE RECORD last winter. My wife's term of gestation ended in March; she always had been in delicate health; there was considerable of the fever in our city, and fatal in many cases, one young lady dying with it only a few doors from us a week or two before my wife's confinement.

It will not be hard for any one to imagine my condition of mind as the time passed. Whether I was to follow the advice of our most enlightened teachers on the subject or not constantly worried me, as doubtless it does many others in similar cases now.

Finally, however, I followed the advice of our Southern brother, who advised throwing away the bed-pan and having the patient sit up several times a day to urinate, and used no internal wash of any kind, but kept every thing scrupulously clean around her. My wife did perfectly well without any trouble, and I for one am convinced that it is wrong to fully follow the advice of one of our teachers and keep the patient austerely on her back for fear of post-partum hemorrhage. To more fully indicate my feelings I will add that for the month of March I refused to attend other cases, and turned away ten, I think, as I for one feel fully convinced that the fever is very often carried to patients both by the physician and also by the nurse.

After a few weeks my wife lost her milk and was unable to nurse the baby at all. Now I was in another trouble. From my own, and the experience of others, I knew that a bottle-fed baby, here in the city, stood a very poor show for living, and that many that did live were poor, feeble, emaciated little beings. I read up almost everything on the subject of infant food, and tried some of the well-known preparations, in combination with milk, which I never fully gave up, but they did not seem to work satisfactorily. I sent the baby in the country, but it was troubled there more than ever, during a wet period in July which we had.

Finally, I got extractum pancreatis and followed the directions, only I used more than half water, and when he was troubled the most and his food seemed to pass entirely undigested, I used two-thirds water. The baby began to improve at once, and is now one of the healthiest babies around here. I kept him in the country—Orange County—where he could have fresh morning's milk, until near the middle of this month, September. When born he weighed a little less than eight pounds; now he is one week over six months and weighs almost three times as much, his flesh is solid, and he looks far better, and is as large as many babies one year old. I continued to use the pancreatis, but do not follow the directions. I take nearly two-thirds milk off the ice, add the pancreatis and soda, then add hot water and feed at once. At night I prepare two bottles and put on ice, or outside the window when cool, although we rarely need but one, and often do not use any. If needed in the night I heat on an alcohol stove in a few minutes, and give at once. The good derived from the pancreatis is all, or nearly all, done in the stomach.

The strangest part of it is that the baby seems to do fully as well, and we think better, on the milk we get here in the city.

My conclusions are that babies can be brought up on milk easily and well under favorable circumstances. Pancreatis and soda aid materially, especially if the food has been passing or rejected in an undigested state.

But I believe it is far more important to dilute the milk with one-half, and often in young babies with two-thirds, water. And above all things keep the feet warm and have the diapers both dry and warm.

Respectfully, G. F.

NEWARK, N. J.

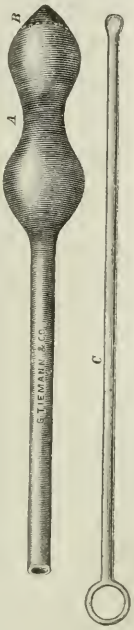
New Instruments.

A NEW MODIFICATION OF BARNES' DILATOR.

By GEORGE COWAN, M.D.,

DANVILLE, KY.

HAVING had some practical experience recently of the difficulties not unfrequently met with in introducing and retaining *in situ* during their expansion the Barnes' dilators, I have had constructed, for future use, by Messrs. Tiemann & Co., of New York, a modification of this apparatus, which, it is hoped, may in some measure remove the troubles met with in their use.



In the Barnes' dilator the pocket into which the probe is inserted for introducing the bag serves as a serious obstruction to its easy introduction, besides being placed externally and to one side of the bag—a very unsuitable point upon which to direct the force which is to guide and push the dilator into its place in the canal. Furthermore, the distal extremity is unnecessarily blunt or flat.

In the second place, it is a flat oval on cross-section, while the cervical canal, when partially dilated, is probably more nearly cylindrical in form. The consequence is that neither the waist nor extremities of the dilator can be expanded so as to give it the form best adapted for its retention when the cervix has been slightly dilated.

The modification which I have had made, and which the accompanying diagram will serve to illustrate, is circular on transverse section throughout its length, and has a tapering distal extremity for its easy introduction into the cervix uteri. The probe which accompanies it is a small brass rod, having a small button-shaped extremity, and is introduced through the gum tube to the inside of the bag, and finally lodged in the centre of the extremity, thus enabling the bag to fold and adjust itself neatly and closely around the probe during its passage through the cervix and along the canal, while the force is applied in the most advantageous position, *i.e.*, inside the dilating bag.

I beg to offer these modifications of the Barnes' dilators to the consideration of the profession as better adapted, I trust, to successfully imitate nature's inimitable provision for dilating the cervix.

A NEW SCROTAL COMPRESSOR.

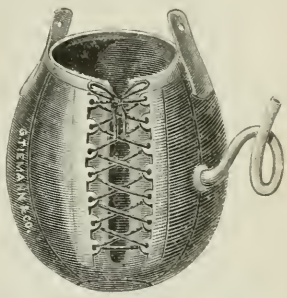
By JESSE HAWES, M.D.,

GREELEY, COL.

LET me call the attention of that portion of the profession who have to deal with inflamed testicles to a device recently made at my request by Tiemann & Co.

It is composed of two rubber bags, the inner one easily distensible, one within the other, and united so as to form an air-tight compartment between the outer and inner layers. This double bag is open on one side from the "mouth" nearly to the bottom; on each side of this opening or "slit" are cemented pieces supplied with eyelets; a small rubber tube perforates the outer layer and is cemented carefully to it. Other pieces are attached to its upper part to aid in suspending it to a waist-belt.

The double bag is sufficiently large to receive the largest swollen testicle. Placing the testicle within the bag, its mouth completely encircling the cord, the slit is carefully closed by lacing; air is then blown from the



mouth, or by a syringe, through the rubber tube into the air-tight space. The compression is perfectly equal and can be exerted to any extent desired; the air is prevented from escaping by simply bending and tying the tube.

Its advantages are these: Hot water can be conveyed into the air-tight space, giving us a warm or hot application. A cloth moistened (*e.g.*, with a lead and opium wash) can be applied about the testicle before placing it in the compressor. One compressor will fit all sizes of testicle. There is no need of shaving the scrotum. It is applied in a moment. When the swelling has decreased the elasticity of the rubber still continues to exert a moderate pressure, and the patient himself may in a moment increase the pressure if it is desired. In short, in my experience, its cleanliness, its perfectly equal compression, the ease with which it is managed, and the comfort it gives the patient, seem to fill every requirement that a compressor should have.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 26 to November 1, 1884.

ALDEN, C. H., Major and Surgeon. In addition to his duties at Fort Snelling, Minn., to perform the duty of attending surgeon at Department Headquarters. S. O. 127, Headquarters Department of Dakota, October 23, 1884.

TOWN, F. L., Major and Surgeon. Assigned to temporary duty as Post Surgeon, Fort Clark, Texas. S. O. 145, Department of Texas, October 27, 1884.

BENTLEY, EDWIN, Major and Surgeon. To be relieved from duty at Fort Clark, Texas. S. O. 145, Department of Texas, October 27, 1884.

WILSON, W. J., Captain and Assistant Surgeon. Assigned to temporary duty at Fort Trumbull, Conn. S. O. 220, Department of the East, October 27, 1884.

CORBUSIER, W. H., Captain and Assistant Surgeon. Assigned to duty at Fort Bowie, Arizona Territory. S. O. 99, Department of Arizona, October 22, 1884.

LA GARDE, L. A., Captain and Assistant Surgeon. Assigned to duty at Fort Ellis, Montana Territory, relieving First Lieutenant G. E. Bushnell, Assistant Surgeon U.S.A., who, upon being relieved, will report for duty at Fort Snelling, Minn. S. O. 126, Department of Dakota, October 22, 1884.

EVERTS, EDWARD, First Lieutenant and Assistant Surgeon. Leave of absence extended one month. S. O. 107, Headquarters Division of the Pacific, October 21, 1884.

MCCAW, WALTER D., First Lieutenant and Assistant Surgeon. Ordered from Fort Craig, New Mexico, to Fort Wingate, New Mexico, for duty. S. O. 92, Headquarters District of New Mexico, October 21, 1884.

Official List of Changes in the Medical Corps of the U. S. Navy, during the week ending November 1, 1884.

BEARDSLEY, GROVE S., Surgeon. To Washington, D. C., for examination preliminary to promotion, and as to qualifications for sea duty. October 31, 1884.

CRAIG, THOMAS C., Passed Assistant Surgeon. To the Alliance for temporary duty. October 31, 1884.

GARDNER, JAMES E., Passed Assistant Surgeon. To the Naval Hospital, Norfolk, Va. October 28, 1884.

HALL, JOHN H., Passed Assistant Surgeon. From the Naval Hospital, New York, to the Navy Yard, Mare Island, Cal. October 29, 1884.

HORD, WILLIAM T., Medical Director. To continue duty as member of the Retiring Board until January 1, 1885. October 27, 1884.

LOVERING, P. A., Passed Assistant Surgeon. To the Naval Dispensary, Washington, D. C., for temporary duty. October 27, 1884.

TURNER, THOMAS J., Medical Director. To continue duty as member of the Retiring Board until January 1, 1885. October 27, 1884.

STEELE, JOHN M., Passed Assistant Surgeon. To the Naval Hospital, New York. October 29, 1884.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending November 1, 1884:

Week Ending	Typhus Fever.	Typhoid Fever.	Scarlet Fever.	Cerebro-spinal Meningitis.	Measles.	Diphtheria.	Small-pox.	Yellow Fever.
Cases.								
October 25, 1884	0	53	29	5	45	45	0	0
November 1, 1884	0	51	29	2	51	67	0	0
Deaths.								
October 25, 1884	0	13	6	5	4	33	0	0
November 1, 1884	0	14	0	2	8	33	0	0

THE OWNERSHIP OF A MEDICAL CURIOSITY.—The newspapers report a very curious case in a Virginia court. A police officer of the city of Petersburg, named William Shank, was for a considerable time visibly growing weaker and thinner, while his appetite continued enormous, when one day last week he vomited a hideous-looking lizard about ten inches long and two inches in circumference. The lizard was dead when ejected, and was thrown away. It was found and presented to Dr. John B. Hartwell, a homœopathic physician, who put it in alcohol to preserve it. Dr. Shank, a brother of the policeman, heard of this and demanded the specimen from Dr. Hartwell, who agreed to give it up if payment was made for the trouble and expense of preserving the curiosity. Dr. Shank refused to make any such payment, and brought suit in one of the inferior courts for unlawful detention, and secured judgment against Dr. Hartwell. The latter has appealed the case to the Hustings Court, and the respective claims of the two physicians will there be determined.

THE QUESTION OF ISOLATION IN THE INFANT HOSPITALS OF PARIS.—If one may judge from the numerous complaints appearing from time to time in the medical journals of Paris, the management of the hospitals in that city is far from being satisfactory. Among all the papers the *Progrès Médical* is conspicuous for its increasing efforts to bring about reforms in this department of the government. In a recent editorial it takes the Administration de l'Assistance Publique sharply to task for its culpable neglect in the matter of isolation in the hospitals for children. It is only within the last five years that any pretence has been made of keeping children with diphtheria apart from the other inmates of the hospitals, and in one of these a separate pavilion for diphtheria patients was only erected in May, 1882. But as far as other diseases are concerned there is not at the present day the slightest provision made for isolation. So glaring is this evil and so well known that, as was asserted not long ago by Dr. Maunoir, these hospitals have a reputation among certain portions of the population of being where superfluous children can be lawfully and at the same time effectually disposed of. In one of the three services of one of the three hospitals in the year 1881, fifty-two children contracted measles in the wards and thirty of these died. By a simple process of addition the writer calculates that two hundred and fifty children are sacrificed in the three hospitals every year by measles alone, and by measles contracted within the hospital walls He adds that by a low estimate the number of victims of contagion from all diseases in the infant hospitals of Paris may be set down at five hundred annually. Such a state of affairs seems almost incredible, and one would suppose that the facts in the case could never have been presented to the authorities. Yet the writer asserts that it is not through ignorance that the administration sins, for its attention has been called time and again to these and other abuses, but without avail. The authorities sit by supinely and fold their hands while five hundred little innocents are sacrificed every year to their brutal indifference. We are accustomed in this country to rail against our public officials and to think that in no other land are the people's servants so indifferent to the people's wants. But very few citizens of New York would care, we imagine, to exchange our Commissioners of Charities and Correction for the Administration de l'Assistance Publique of Paris.

THE MENTAL STATES INDUCED BY FRIGHT.—The *Wiener Medizinische Wochenschrift*, of July 19, 1884, contains an abstract of an interesting account of the earthquake at Ischia, written by Dr. Fazio, an eye-witness of the scene. The emotions awakened by the catastrophe were of the most varied character. During the fifteen seconds that the shock continued everybody stood still, seemingly rooted to the ground with terror. Men were weak in the knees and shook as with ague, feeling as though they were about to fall, but none of them had convulsions, delirium, or syncope. But soon this stillness was broken by loud cries and howls, and every one rushed toward the shore. Then women and children fell into convulsions or appeared to be semi-paralyzed and speechless. Rudeness and brutality were mingled with self-sacrifice and heroism of the most exalted character. Six hours after the catastrophe the stillness of death reigned over Casamicciola. Men wandered about the ruins half clad and silent as if risen from the grave; women were excited and hysterical; children of eight or ten years seemed dazed and stupefied, while smaller children stood around unconcernedly eating whatever they could find in the ruins. It is most interesting to see the different ways in which individuals were affected by the shock. The keeper of a refreshment booth who had lost everything kept offering his delicacies to those who passed by, just as though everything had not been swept away. A surgeon, covered with blood and sorely wounded by the fallen beams, was concerned only for his instruments, and inquired after them of everybody whom he encountered. An hysterical woman, who had been bed-ridden for months, jumped up and saved herself by flight, and remained permanently cured. Many who were at first brave and full of energy became later depressed and apathetic, or had convulsions or alternate fits of laughter and crying. Sometimes a melancholia was induced which continued for months, and many became incurably insane. Abortion was very common, and there

were many cases of suddenly arrested menstruation. The sexual appetite was universally destroyed for many days after the earthquake, and in many instances there was also an aversion to food. There were numerous cases of retention of urine, sometimes lasting for days and demanding catheterization. There were several instances in which the hair was whitened by fright, and even some boys of ten to fourteen years showed heads sprinkled with gray. Many of those buried in the ruins exhibited the greatest indifference to their fate, following listlessly with their eyes the motions of those busied in their rescue. A foreign officer whose legs were imprisoned under some heavy timbers drew out a cigarette and smoked it with the utmost nonchalance. One man, as soon as he was pulled from the ruins, shook his rescuer by the hand and presented him with his card. Another, who lay beneath the débris for twenty hours, immediately looked at his watch in order to record the exact instant of his deliverance. A lady who had just been extricated from a mass of rubbish would not budge from the spot until she could ascertain the fate of her pet dog, which was buried with her. One woman who heard a man calling for his daughter, deceived him so cunningly that she was rescued by him before the trick was discovered. Most of the people, however, who were imprisoned beneath the ruins were too indifferent to their fate to attempt any such deception, and most of them had not the slightest idea of the length of time during which they were buried. Most of those who were wounded by the falling buildings underwent the necessary surgical operations without experiencing any pain, though some were hyperæsthetic.

What Constitutes Unchastity.—A curious point as to the proper admission of testimony was presented on the appeal of a case, where the action was for slander in charging an unmarried woman with unchastity. The defendent, in answer, alleged that there was such an increase in the size and such a change in the physical appearance of the plaintiff as to induce him to believe that she was pregnant. One of the witnesses on his behalf was a woman who had borne children, and who was asked if the plaintiff, as to her physical appearance, appeared like women do when they are pregnant. This question was not allowed, and the appeal from the ruling was the main point to be decided. The court held that it was proper to ask a witness his opinion whether a person was drunk, because that fact is better determined by the direct answer of the witness than by any description of the person's conduct, and that there was a similarity between such a case and that where the fact of pregnancy was involved. The court was of the opinion that "if the appearance of the plaintiff, from any cause, was such that women who had had experience would testify that she appeared like a pregnant woman physically, the testimony certainly was important to mitigate the damages to which the defendant might be subjected. And if the plaintiff insists that the witnesses should have stated the facts in detail, in order that the jury might judge whether plaintiff's appearance was like that of a pregnant woman, it is obvious that no description of enlargement of size and the like would convey an accurate idea of the plaintiff's whole appearance." It was therefore decided that it was proper to ask the opinion of the witness whether the appearance of the plaintiff was like that of a pregnant woman.

Is Cannibalism Necessarily Murder?—A very interesting case will shortly be brought to trial in England, to determine whether cannibalism is necessarily murder. The facts are these: The yacht Mignonette, under Captain Dudley, was disabled in a gale between Madeira and the Cape Colony last July, and the crew, consisting of the captain, two men, and a boy, took to the boat. They soon exhausted their small supply of provisions, and no help was at hand in mid-ocean. After a little they caught a turtle, and this sustained life for some days. When this was eaten, starvation began. After some days it was proposed that they should cast lots to see which should die to save the others, but this plan was rejected. When fifteen days had passed without food, after further debate it was decided that the boy, who was very weak and sinking fast, should die, and the captain, after asking God to pardon what he was about to do, killed the youth. For three days the survivors subsisted on the boy's flesh, and then a passing vessel picked them up and took them into Falmouth. Captain Dudley did not conceal the facts, but promptly reported them, not expecting, apparently, that he would be held criminally liable. The authorities of Falmouth, however, arrested him on his own sworn statement, and the trial for murder will soon take place. It will be seen that these circumstances are quite different from those of the Greely party, as there only the flesh of the dead soldiers was eaten. The moral question is much the same, however, and the Dudley case will certainly give rise to great discussion as to the propriety of eating human flesh under any circumstances. It should be remembered that in the case of the Mignonette the killing of the youth, no doubt, saved the lives of the others, and had not this been done all would have probably died. This does not affect the moral aspect of the case if the act was wrong under any conditions, nor does the further fact that the boy would soon have died from natural causes; but these circumstances will inevitably have some effect upon a jury called upon to determine whether Captain Dudley shall die for his act. The question of insanity will also assume a prominent position on the trial, for it is certainly a matter for investigation whether persons exposed to the weather for fifteen days in an open boat, without any food, are responsible for their acts. The outcome of the trial it is not difficult to surmise, for no matter whether public sentiment abstractly condemns Captain Dudley's conduct or not, it is not at all likely that any jury will bring in a verdict of guilty of murder. The chances are wholly in favor either of a disagreement or acquittal.

Sublimate Injections in Joint Diseases.—Professor Vogt has obtained good results in three cases of so-called gonorrhœal rheumatism of the knee by intra-articular injection of corrosive sublimate. He employed a solution of bichloride of mercury, 1½ grain; chloride of sodium, 15 grains; distilled water, 12 drachms. Of this solution 45 to 75 minims were injected into different parts of the joint. The injections were repeated every four days, but how long the treatment was continued the author does not state. At the time when these cases were reported he stated that the cure could be regarded as established, massage and passive motions being all that was necessary to restore the functions of the joint. In other non-specific bone and joint diseases a somewhat extensive employment of this mode of treatment leads the author to believe that "in certain cases much can be accomplished by intra-articular injections of corrosive sublimate."—*Centralblatt für Chirurgie*, August 23, 1884.

Does Decapitation Cause Instant Death?—We noticed recently some experiments made by M. Laborde with the head of Campi, who was executed in Paris for a murder, which almost seemed to show that life might be retained for a time in a decapitated head by supplying the brain artificially with blood. The publication of these results in the *Revue Scientifique* has called forth a communication from another writer who witnessed an execution in Saigon some years ago, a brief account of which we abstract from the *Tribune Médicale* of August 10, 1884. Decapitation in Annam, it seems, is performed by a single sword stroke on the neck, the criminal kneeling down and being forced to flex the head so as to separate as widely as possible the vertebræ. Thus it sometimes happens that the cord is severed by a clean cut without being either contused or concussed. The writer being desirous to ascertain whether consciousness were retained in the separated head, attracted the attention

of the criminal to himself by speaking in a loud tone to one of the officials just before the execution took place. He was successful in this, for the condemned man looked up and gazed intently at the speaker for a moment. He then knelt down and received the death-stroke. It so happened that the head in falling did not roll, but rested upright on the sand in such a way that the flow of blood from the veins of the neck was arrested. In an instant the eyes were opened and fixed themselves upon the writer, who stood very near. He moved quickly to one side and the eyes followed him; then he returned more slowly to his former position, and the eyes turned again in that direction. They followed him but for an instant, however, and were then suddenly turned away, while an agonized expression overspread the features, the mouth opened spasmodically, and the face seemed to gasp for breath. The movement of the jaw overturned the head and it rolled on the sand and gave no further signs of life. Could the cerebral circulation have been maintained in this case as it was in that of Campi, by connecting the vessels with an opened artery of a dog, the results might have been startling enough to disturb even the most phlegmatic experimenter.

The Value of Cinchonidia.—Dr. J. Weichselbaum, of Savanna, Ga., writes us in reference to the editorial in The Record of July 19th, upon the value of cinchonidia. He states that "in the female ward of the Savannah Hospital, the service of Dr. R. J. Nunn, we have been using the sulphate of cinchonidia for some time. We use the following formula:

℞. Cinchonidia sulph..... gr. v.
Sodii bicarb..... gr. v.
M. S.—One dose for adult;

with the same result that we had with the sulphate of quinine. We used it in all cases we would have used the sulphate of quinine. We never had any of the trouble complained of by Professor J. Marty." Our correspondent adds that of late he has been using the alkaloid cinchonia given with soda, and has had equally good results. The inference from Dr. Weichselbaum's experience is that quinine is no safer or surer than its cheaper allies. This is against the experience of the profession, and invalidates completely Dr. W.'s observations.

A Case of Cancer of the Pancreas—Autopsy.—Dr. F. W. Epley, of New Richmond, Wis., sends us the following: "In view of the fact that the literature upon affections of the pancreas is exceedingly limited; that some of our standard works on pathology pass over the organ with the simple remark that 'the pancreas is seldom examined for disease,' and give no further directions in regard to the post-mortem examination of said organ, and that in the light of more frequent autopsies consequent upon death from obscure causes we can approach nearer the truth in these pathological assertions, I have reached the conclusion that it is the duty of every medical man to report cases which come under his notice where obscure or questionable cases have been cleared up by an autopsy. On May 25, 1884, Sam M—— came into my office and told me he wanted me to see if I could find out 'what in h—l ailed him.' I give his own words, for they are not void of significance in this case. He stated that he had begun to feel badly soon after walking a long distance through snow-drifts in the February preceding. He lost his appetite; had some uneasiness about the epigastrium; had a nasty taste in his mouth; had not slept a wink for weeks, and 'then these d—d black janders come onto him and he wanted to *die* if I couldn't give him something to relieve him.' He was restless, weak, but constantly moving, and was even more impatient than his language indicates. He was a farmer, well-to-do, always quiet and always industrious. Upon examination I found him only fairly nourished; evidently losing flesh; extremely *icteric*, and covered with an eruption simulating bromism, which kept him constantly scratching. His stools were *entirely devoid of color*, except that of prepared chalk. This peculiarity was constant. I found, about two inches to the right of the umbilicus, a small hard tumor, apparently about the size of a small tea-cup, but more pointed. It was hard but freely movable. It was not easily to be seen, but by close attention the abdominal parietes could be seen to glide over the tumor. I diagnosed malignant disease, either in liver or structures closely approximating it, and contrary to my custom gave up the case at once, communicating the facts to his wife. He went to other physicians, and finally struck a lead on two homœopathic doctors, who 'cured him till he died' on December 10th, following. Autopsy revealed cancer, scirrhous form, in head of pancreas, which had drawn up about the common duct of the liver to such an extent that it was impossible to separate the duct, or in fact to distinguish it by the naked eye from the pancreatic tissue. *Hence the jaundice.* There was no obstruction in bowels or stomach, and no other structure was involved to any extent, except a portion of the lesser omentum. It occurs to me that the disease *must* have originated in the head of the pancreas, thereby occluding the common duct and occasioning the early and persistent jaundice. The tumor near the umbilicus proved to be a distended gall-bladder. The liquid it contained was of a pearly hue and quite viscid."

Treatment of Skin Diseases at Vienna.—A correspondent of the *British Medical Journal* writes: "In Professor Kaposi's wards the permanent bath-beds are in constant use. Burns, ulcers, and obstinate syphilides are here treated; in the latter cases, weak solutions of perchloride of mercury may be used with advantage; in the cases of burns, the patients express themselves as being most comfortable; after being in the 'bed' a few moments all pain is lost, and there is no dread of change of dressings, for none are used. Not only does the slough separate and the wound clean, but cicatrization progresses, it is said, more rapidly in the water than under any other treatment. Psoriasis is usually treated with pyrogallic acid, 10 per cent. in traumaticin; goa powder in the same combination is also used. In the treatment of superficial lupus, iodoform in solution, with collodion or pyrogallic acid as an ointment, is used; the former is usually applied after the affected part has been rubbed with a strong solution of caustic potash. Several cases of lichen scrofulosorum have been effectually treated with cod-liver oil internally, and as an external application. A few weeks ago a young man was admitted into the wards suffering from what was at first supposed to be merely a case of severe intertrigo, affecting the perineum and surrounding parts. The severe general disturbance, however, led Professor Kaposi to diagnose impetigo herpetiformis. This disease, of which only about a dozen cases are on record, is usually found in women, and appears to be in some way connected with pregnancy and the puerperal period; one case, related by Heitzman, occurred about the time of the climateric. Two cases only are on record where recovery has taken place. The term herpes pyæmicus, of Auspitz, was upheld, as the disease is one which is probably pyæmic in origin, while its progression is marked by the formation of small, closely aggregated, innumerable bodies, which are pustular from the commencement. From the first the case was associated with high and irregular temperatures, and the patient was treated with antipyretics, simple dressings being applied. The affection, however, gradually spread upward over the abdomen, and smaller patches appeared elsewhere. The patient gradually sank into a somnolent condition; later he was removed into one of the permanent bath-beds, where he appeared more comfortable, and the open surfaces more healthy; it was specially noticed that this change produced, in addition, immediate and sustained lowering of the temperature. The patient, however, gradually sank, and on *post-mortem* examination general peritonitis with effusion into the peritoneal cavity was found."

A NEW THERAPEUTIC USE FOR COCAINE.

By F. H. BOSWORTH, M.D.,

NEW YORK.

In using a solution of cocaine in the nasal cavity for its anæsthetic effect I have observed an action which has, as far as I know, not been recorded. When the solution is applied to the mucous membrane it is followed in about twenty or thirty seconds by a very notable contraction in the venous sinuses underlying the part which it reaches, and as the application is continued over the whole membrane covering the lower and middle turbinated bones these sinuses become so rigidly contracted that all the blood which they may have contained is absolutely expelled, and the membrane clings closely to the bony structures, which then become visible in absolute outline.

This action of the cocaine was so entirely unexpected to me in the first case in which I observed it that I continued my observations in a number of cases, and in no single case out of over forty observed carefully has it failed to produce the same result. Every drop of blood was expelled from the erectile tissue in each case. The strength used was a two per cent. solution, and it was applied by means of a pledget of cotton wrapped on a small probe. The effect was usually observed in a few seconds; entire depletion of the sinuses of the whole cavity being accomplished in about three minutes, the production of anæsthesia, as a rule, requiring a longer time.

The practical value of the use of the cocaine cannot, I think, be overestimated, for we possess no other remedy which can be depended upon to produce this result. The morbid conditions in which I observed its action, and in which it is of especial value, are as follows:

Hypertrophy of the nasal mucous membrane.—This is by far the most frequent cause of a nasal catarrh, and its rational treatment demands the use of caustics or other destructive agent. The use of any caustic is followed by an intense turgescence of the venous sinuses of the nose, which is a source of distress for hours, and even days, after its use.

I have cauterized the mucous membrane of the nose in twenty-seven cases since I observed the above-mentioned action of cocaine. The application was rendered comparatively painless by the drug, but the turgescence of the membrane came on in a few minutes after the caustic was used. By gently bathing the swollen part with the cocaine the turgescence subsided permanently, and the cauterization was accomplished without pain or the subsequent discomfort which so generally follows its use.

Another and very notable value of this action of the cocaine is as an aid to diagnosis in these cases of hypertrophy. In an ordinary case of this kind it is not possible to determine, on ocular inspection, how much of the swelling of the membrane is due to connective-tissue hypertrophy and how much is due to turgescence of the venous sinuses. By applying the cocaine to the membrane the element of venous turgescence is entirely eliminated, and the amount of genuine hyperplasia can easily be recognized.

Acute coryza.—In an ordinary cold in the head the prominent condition is the venous turgescence. I applied the cocaine in seven cases of the affection and in each case the same result was observed. The venous sinuses were completely emptied, and the nasal passages remained absolutely clear. The relief in five of these cases, which I saw subsequently, lasted from twelve to twenty-four hours. That is, in these cases the nose did not become "stopped up" again for from twelve to twenty-four hours, and then the relapse was only partial. The colds were broken up. For a cold in the head, then, cocaine, it seems to me, promises to afford us a remedy, which is not only prompt, but certain, and by prescribing it either in the form of spray or as a snuff, we can place in the hands of our patient a ready means of relief for that most distressing symptom of a cold, the "stopped-up nose.'

Nasal polypus.—The introduction of an instrument into the nasal passages usually causes a swelling of the membrane to such an extent as to seriously interfere with the inspection of the parts. In operating on four cases of polypus in the past week, this troublesome feature of the operation was entirely eliminated. The venous congestion was thoroughly kept down, and so clear a view into the upper regions of the nose was obtained that it was made a comparatively easy matter to recognize and remove even the smallest growths. But of still further importance was the fact that in no case was there other than the most trivial bleeding. In removing nasal polypi with the snare the troublesome bleeding is never from the mucous membrane, but from the venous sinuses which may be opened. In the four cases above mentioned, these sinuses were rigidly contracted by the cocaine, and hence the bleeding from the operations was but a trivial matter.

Hay fever.—The morbid condition of the nasal passages in an exacerbation of this disease is undoubtedly a turgescence of the venous sinuses, probably from a paresis of the vaso-motor nerves which are distributed to the coats of these vessels. I have had no opportunities of observing the action of cocaine in an acute exacerbation of hay fever, but I have applied it in two cases in which the symptoms were present to a mild extent. Both were cases of autumnal catarrh, commencing August 26th and lasting till the first frost. In each of these cases the result was the same. There was complete relief from all the symptoms.

The above-mentioned cases may not, perhaps, be conclusive as regards this action of the cocaine, but it certainly goes very far toward establishing its value. I used it in forty cases, all presenting marked swelling of the nasal mucous membrane, both from chronic and acute causes, and in every case the result was the same. There was an absolute and complete subsidence of the turgescence of the membrane and the sinuses were entirely emptied of their blood.

Among the observed symptoms of the internal administration of cocaine is the production of tetanic muscular contraction. The only explanation of its above observed action is that it produces the same action upon the muscular fibres which are found surrounding the venous sinuses which form the erectile tissue of the nose. Its action, it should be mentioned, is confined to the venous sinuses, for I have never observed that it exerted any influence upon the capillary circulation of the mucous membrane of any region. A tetanic contraction of the muscular fibres which surround the venous sinuses in the nose could only produce the condition I have observed,

for when the cocaine has had time to exert its action, the mucous membrane is seen to cling to the turbinated bones with a rigid clasp which can only be described as tetanic.

While, then, we have in the cocaine a local anæsthetic of very great value, I think we also have a therapeutic agent of inestimable importance, and which we have every reason to believe will be efficient, 1, to control the exacerbation of hay fever; 2, to relieve the most distressing symptoms of an acute coryza and curtail its duration; 3, to control the painful and distressing reaction which results from the use of caustics or instruments in the nasal cavity; 4, to completely empty the venous sinuses of the nasal mucous membrane, and thereby afford a thorough ocular inspection of the cavities; 5, to largely eliminate from our minor operations in the nasal cavities the troublesome hemorrhage which so often occurs, and to control epistaxis from whatever cause.

SOME NOTES ON HYDROCHLORATE OF COCAINE.

By N. J. HEPBURN, M.D.,

OPHTHALMOLOGIST TO THE DEMILT DISPENSARY, NEW YORK, ETC.

In the course of some experimental inquiries into the anæsthetic action of hydrochlorate of cocoaine, I observed some facts which may be of interest at this time.

A two per cent. solution of the salt (Merck's) was used in each instance, injected under the skin of the arm by means of a hard-rubber hypodermic syringe with gilded steel needle.

On October 16, 1884, I injected six minims of the solution at 7.30 A.M. In one minute and a half there was partial anæsthesia of the skin and subcutaneous cellular tissue for a space of eight lines in every direction from the centre of the injection. In four minutes the anæsthesia was complete over the same area, which was bounded by a hyperæsthetic line separating the anæsthetic portion from that of normal sensation. The injection was repeated every five minutes in adjacent spots with precisely similar results, until forty-eight minims had been used.

By this time the general physiological effects of the drug began to manifest themselves so plainly that it was deemed unadvisable to continue the experiment. These effects were increased frequency of the pulse, increase of one-fourth in the number of respirations per minute, an agreeable feeling of warmth, moderate mydriasis, slightly crossed diplopia, and agreeable hallucinations with closed eyes, which fancies disappeared when the eyes were opened. The power of locomotion was very slightly interfered with. These symptoms gradually disappeared, until, two hours after the last injection, nothing abnormal was noticed.

Two days later another trial of the same nature was made, when it was found possible to carry the number of six-minim injections to sixteen before the general disturbance became too marked to continue.

In a third trial, October 22d, using eight minims at each injection, it took sixteen injections also to produce the same toxic effect. On this trial the disturbances were more marked, and continued at least four hours, followed by a period of wakefulness lasting nearly all night.

The most noticeable of the sensations observed at this last trial were a general impairment of cutaneous sensibility, a feeling as if walking on cushions, a tendency to walk on the heels, and a sensation on grasping an object as if something spongy were interposed.

367 WEST TWENTY-THIRD STREET.

TWO THOUSAND DOLLARS FOR A BODY.—The daily papers mention a recent case in one of the Indiana courts where a medical college was obliged to pay $2,000 for having robbed a grave to secure the body for dissection. The name of the college is not given.

TRACHEOTOMY IN CROUP AND DIPHTHERIA.

By SIMON BARUCH, M.D.,

NEW YORK.

It is "a healthy sign of the times" when the discussion of worn and trite subjects of practical import occupies the minds of our profession, and when the search after novelties is for the nonce in abeyance. The subject of tracheotomy in croup and diphtheria has long been the theme of anxious and earnest inquiry. Its literature has grown to unwieldy proportions, as is witnessed by the fact that the library of the Surgeon-General's office contains five hundred and eighty-four separate treatises, upon the subject of tracheotomy in croup and diphtheria, occupying in their enumeration twelve and one-half columns of the index catalogue. The paper read recently upon this subject before the Obstetrical Section of the Academy, by Dr. Joseph Winters, presents an able, lucid, earnest, and logical defence of this life-saving operation. I am sure its careful perusal will serve to embolden the timid to advise and execute the operation more early and more frequently, and it will encourage the bold in pressing its advantages more persistently. I make this small contribution to the subject in order to elicit from practitioners in all sections of our country an expression of opinion. It is to be hoped that the interest in the subject will not be allowed to flag, as has so often been the case in its history, but that the practical tendency of the modern medical mind will keep it before the profession until its true merits are definitely ascertained and recognized. It will be the most important outcome of the present agitation of the subject, if general practitioners who in remote country districts and smaller towns frequently do other surgical work, can be persuaded that tracheotomy is not a hazardous operation, and that as a surgical procedure it does not require extraordinary skill or knowledge.

It is a sad, too sad fact, that precious time is often lost in the search for a surgeon; and that at other times the procedure is regarded by parents in the light of a capital operation, which handicaps their child in its struggle for life. These reasons operate in favor of delay until the operation becomes one of emergency. It is a fact to be remembered, that one successful tracheotomy for croup or diphtheria will do more to neutralize the groundless apprehension, in the minds of physicians and laymen, than all the statistics marshalled by high authority. As an illustration I will mention that two year ago Dr. Abram Jacobi performed a successful tracheotomy on a child in Carmansville, a suburb of this city, and since that time there is rarely an objection made to the operation. Within the past six months I have done it three times in that section of the city, and I cite these cases in order to illustrate the chief aim of this paper which is to emphasize the necessity for an early operation. On May 21, 1884, I was asked by Dr. William Frothingham to see a boy, three years of age, who had been under treatment for diphtheria for several days and was rapidly growing worse. The turpentine treatment, so much lauded in Germany, was advised and adopted, but without avail. Patient became cyanotic, and tracheotomy was adopted as a *dernier ressort*. By the light of a kerosene lamp, and amid the wailing of parents and friends, the gasping child was placed upon the table. He was so completely cyanosed that no anæsthetic was necessary. When the trachea was reached pulse and respiration ceased. The trachea was quickly opened, the tube inserted, and in a moment the inrush of air brought on cough and an expiratory effort. The color returned to the face, and the child revived, taking nourishment, which he had refused for many hours, because of his intense preoccupation with the struggle for breath. It was too late, however. The child expired in twenty hours.

To the second case I was called by Dr. Goodrich on September 10, 1884. A boy, aged seven, was discovered

during the night to be ill. When the doctor was called to him he made a diagnosis of naso-pharyngeal and laryngeal diphtheria. I saw him a few hours later, and confirmed the diagnosis. The breathing was stridulous, there was episternal and abdominal retraction, but no cyanosis; laryngeal stenosis was unquestionable. Tracheotomy was advised and readily assented to by the physician and the father of the child. Patient was etherized by Dr. W. T. Alexander; there was nothing unusual in the operation except the appearance of a great gush of venous blood when the trachea was opened, although the wound was dry. The incision was thus obscured, but by aid of a finger-nail it was found and somewhat enlarged. The tube was rapidly inserted and hemorrhage stopped promptly. This point will be referred to below. Patient received $\frac{1}{8}$ gr. bichloride mercury every two hours, and 10 ♏. tr. ferri, with 1 gr. chlor. potass., every hour, besides nutrients *ad libitum*. In eleven days he was sufficiently recovered to warrant the removal of the tube, and he is now in perfect health.

On October 7th I was asked by Dr. Goodrich to see another boy, also aged seven, and, like the last patient, in perfect health before the attack. This child had, however, been ill five days without treatment. Stridulous breathing alarmed the parents, who thought the child was simply suffering from a cold. When Dr. Goodrich was called he recognized at once the dangerous character of the malady and advised tracheotomy, to which the parents readily assented, because they were aware of the successful issue of the above-mentioned case. When I saw this patient he was not cyanosed, but there was stridulous respiration, and in all respects the case resembled the last mentioned, except in the longer continuance of the disease. The operation (under ether) was somewhat embarrassed by the deep situation of the trachea, a very large thyroid gland, and the presence of large veins coursing across the line of incision. The gland was drawn upward by a blunt hook, the larger veins held aside, one small vessel tied, and the trachea was now reached without difficulty. When it was opened it was so filled with diphtheritic deposit that the incision was bloodless and the knife grated as if passing through the soft rind of a melon. It is to me a marvel how this child breathed through so narrow a channel without being markedly cyanosed. The tube was readily inserted. Patient revived, countenance became calm and bright, pulse more quiet and regular. But it was too late; he died on the following day from asthenia.

These three cases show clearly the vast advantage of an early operation. The last two cases were circumstanced precisely alike, being of the same age, and in the same social grade, but the one was operated upon very early, the other very late. Statistics have again and again demonstrated the value of an early operation; common-sense is thus aided by experience. It is criminal to wait until cyanosis hangs out the danger signal. Aphonia, stridulous voice, and respiration, the distended nostrils, the heaving chest, and appealing eye point unerringly to the speedy advent of carbonic oxide poisoning.

The patient is dying from asthenia, and threatened with carbonic oxide poisoning in addition. We are pouring stimulants, nutrients, and tonics into his stomach with a view to avert or counteract asthenia. So assiduously is he "supported," that he is often scarcely allowed to sleep. Of what avail are all our "supporting measures" when he is slowly approaching strangulation, when the respiratory passage is encroached upon more and more every moment, so that he cannot obtain sufficient oxygen to carry on the machinery of life? I take it that oxygen is *facile princeps* among stimulants; it is the great life-saving principle, the grand protecting ægis against disease and death. All our energies in sanitary medicine are bent in the direction of increasing the supply of oxygen to our dwellings, schools, prisons, etc.; all our best efforts in the hygienic treatment of many of our patients are in the direction of increasing the amount of oxygen in their lungs. Why, then, stand idly by when in diphtheria our little patient is hour by hour robbed of the all-important element? How absurd it is to supply artificial stimulants while nature's great stimulant and sustainer is withheld! The patient prays for air, and we give him milk and brandy; "he asks for bread, and we give him a stone." It cannot be too earnestly urged upon the practitioner that it is his duty to watch as anxiously for, and guard against, the oncoming of the threatening air famine (carbonic oxide poisoning) as it is to watch and guard against the approach of the food famine (asthenia). Just as we increase the stimulants, when the pulse flags, just in the same measure should we increase the oxygen when the respiration flags. Indeed it is an accepted axiom of physiology that man can exist far better with a limited supply of food than with a limited supply of oxygen. And yet physicians hesitate when they clearly see the advent of cyanosis and consequent asphyxia in these cases. He who hesitates is lost, and will sadly regret his indecision.

Especially is it the duty of the attending physician to operate early on the first indication of abiding laryngeal stenosis, when he recognizes the fact that tracheotomy is really not a dangerous operation. From a somewhat extensive experience I may be permitted to state that tracheotomy in children is rarely followed by shock or accompanied by hemorrhage, which latter is readily stanched by pressure forceps, *serres-fine*, or ligatures. It is an operation which may be performed without difficulty by an ordinarily steady hand and cool head. Hence it does not, in my opinion, as a surgical procedure, enhance the patient's danger, if undertaken early. When I lived in the South I was often consulted for foreign bodies in the air-passage. These were sometimes grains of Indian corn, but most commonly they were the seeds of the watermelon. This fruit is largely cultivated in the section of South Carolina in which I resided. The country people regard it as so harmless that children of very tender age even are permitted to partake of it. Every farmer has "a patch of melons;" hence their use is universal. It is not uncommon, while riding through a plantation in midsummer, to see a little negro child sitting or lying near a big watermelon, and with its tiny hands digging out the juicy mass and stuffing it into its mouth. The result is that these babes, as well as older children, white and colored, occasionally "get the seed into the wrong throat," and are brought to the physician. The history of such cases of "croup" is usually clear. Rarely did a summer pass, during my practice of fifteen years in that section, without one or more cases of this kind being brought to me by the parents, or sent by country practitioners.

With the exception of one case, the removal of the foreign body was always advised and executed. Under chloroform I have never found the operation presenting serious difficulty; the foreign body usually presents itself at the tracheal incision, or is expelled into the room with the strong expiratory effort which always follows the latter. The wound is closed and heals within a week; there is usually no shock, no fever, and the only trouble I have encountered is a slight dysphagia on the third and fourth days. I can recall only one fatal case of this kind, a negro boy, sixteen years of age, in which the nature of the foreign body was unknown and was not found. My friend, Dr. T. T. Robertson, of Winnsboro, S. C., has obtained quite a reputation as an operator for watermelon and corn-seeds, having done tracheotomy many times successfully. It cannot be denied that the presence of a tube in the trachea seriously complicates the case, but the advantage of a new and perfect air-channel counterbalances this evil.

The manual of the operation differs somewhat in the hands of different surgeons, and it is well for the novice to obtain all the information he can on the "points" which experienced operators give. It is important to strike the junction of the sterno-hyoid muscles, and avoid cutting

into the muscular fibres. If the latter happens, the operator will find it difficult to reach the trachea, and there will of necessity be a larger wound surface and more hemorrhage. To obviate this difficulty I invariably divide the cervical fascia upon the grooved director, and never attempt to enter between the sterno-hyoid muscles *from above*. Placing thumb and forefinger upon either extremity of the sternal manubrium, the median line is easily obtained, the handle of the scalpel readily enters between the muscles as they lie separately attached to the sternum. Upward pressure with the handle acts as a wedge to separate them. The wound should be as dry as possible ere the trachea is opened, all vessels being secured. When the incision, which should be ample always, is made into the trachea, the supreme moment of the operation arrives. There is a struggle and an ugly gurgling of air and blood, which readily disconcert the novice. At this moment the surgeon should be calm, and steadily press on to the goal—the insertion of the tube. If blood wells up from the wounded trachea or from unseen veins, the operator should not stop to stanch the hemorrhage. The tube is the best hæmostatic agent, and through its unyielding channel portions of membrane and blood are more readily expelled or drawn than through the tracheal wound, held open by retractors. I am sure that lives have been lost in the effort to check the hemorrhage here referred to, and by delaying the introduction of the tube.

The after-treatment should be vigorously pushed by constitutional measures and local inhalations of moist air. It is a too common practice to fill the room with vapor and exclude the air. The patient needs a moderately warm and moist atmosphere, but *he needs oxygen more*.

43 East Fifty-ninth Street, October 24, 1884.

CEREBRAL LOCALIZATION—THE CENTRES FOR VISION.

By PHILIP ZENNER, A.M., M.D.,

cincinnati, o.

(Continued from p. 460.)

SOUL-BLINDNESS.

When Munk[1] removed the central part of the visual area of dogs he produced a condition which he termed soul-blindness. The animals, though evidently retaining the sense of vision, no longer recognized familiar objects. He supposed their brains to have been robbed of that part in which were stored up the visual images gained from past experience, and that they were, therefore, in the condition of new-born, who see but do not know what they see.

A few words of explanation are necessary to express Munk's views more fully.

An image formed on the retina makes an impression upon the visual area of the brain and is perceived. If, at the same time, the attention dwells upon this image it leaves an impression upon the brain which remains, perhaps permanently. Now if the object is seen again it is compared with this retained visual image and thus recognized as seen before. This retained or memorized visual image may now be brought up in the mind without the external presence of the object, it may appear in the fancy or imagination, or be utilized in thought.

These memorized images are probably received and stored up where the visual impressions themselves are received, that is in the visual areas. But Munk believes that they are stored up in the central part of the visual area, in relation with the central part of the retina, and that when this central part is removed the memorized images are lost also. He believes those images are usually stored up in the central part because for memorizing anything the act of attention is always necessary. Ordinarily attention is only paid to images which fall upon the central part of the retinæ; therefore, according to Munk, memorized images are only stored up in the central part of the visual areas.

Mauthner,[1] on the other hand, believes that Munk's soul-blindness is altogether due to impaired vision, that his dogs do not recognize objects because they do not see distinctly, and that the effects would be altogether the same whether the central parts of the retinæ or the central parts of the visual areas were destroyed.

The difference between these views should be distinctly recognized. Mauthner also believes that the retained visual images reside in the cortex, but he believes that the seat of these images is coextensive with vision itself, whereas Munk believes that, while the whole visual area is devoted to vision, some images are stored up, retained, or memorized in one part of it, some in other parts, and that such images may therefore be lost, while the sense of vision is retained.

Were we only concerned with conditions experimentally produced in dogs, I would not have dwelt upon this matter here, but similar conditions have, of late years, been observed in man, and the subject has obtained, apart from its great theoretical interest, a certain practical value.

SOUL-BLINDNESS IN MAN.

A few years ago Fürstner first reported such cases. Others of a similar character have since been recorded. All of them were cases of general paralysis. The visual disturbances in every instance followed paralytic attacks (apoplectic or epileptic in character), and disappeared again in part or altogether within a few days or weeks. In some instances the mind was so clouded that the observations can scarcely be utilized for scientific purposes; in others the mind was sufficiently clear when the observations were made to give the latter an undoubted value.[2]

A few illustrative cases will now be given. In Fürstner's first case,[3] after an epileptiform seizure with loss of consciousness, a right hemiplegia of several days' duration was found, also a deviation of the eyes to the left, which was of two weeks' duration. A few weeks after this seizure, when the mind was completely clear, it was observed that patient recognized objects with the left eye, but did not appear to see with the right one. At least he did not recognize objects with the latter, and objects brought suddenly before it did not cause any reflex movements, winking, etc. At the same time the pupils responded to light and the fundi oculi were normal.

His vision improved, and it was now noted that when he tried to grasp an object in the hand of the physician he moved his head from side to side, then seizing the arm of the physician, followed it until he reached the hand. He could not count objects without touching them. Often in attempting to touch objects he reached beyond them. In counting small objects he often overlooked some, or counted the same one repeatedly. In counting he would move his head constantly from side to side. At a later period he could recognize small letters, but if the letters were combined to form a word he could neither read the word nor point out the separate letters.

The patient's mind was quite clear and he was repeatedly and carefully examined. It was explicitly stated that there was neither color-blindness, contraction of the field of vision, hemianopia, nor binocular diplopia.

These visual disturbances had almost disappeared when the patient had other paralytic attacks and died shortly afterward. A focus of softening was found in each occipital lobe.

In a number of cases Fürstner observed similar visual disturbances. They always followed paralytic attacks,

[1] See second paper.

[1] Gehirn und Auge, p. 487.

[2] It has been attempted to utilize these cases, especially those of Fürstner, in certain questions of localization, but there are various reasons why they do not answer for this purpose, and that aspect will not be considered here.

[3] Archiv f. Psychiatrie, viii., p. 165.

but usually disappeared in a much shorter time than in the above case. But these peculiar visual symptoms are even more marked in some cases reported by Stenger.[1]

In Stenger's cases both eyes were equally affected. I will briefly relate the two most interesting ones.

In the first, in whom there was already a degree of dementia, there occurred paralytic attacks every four or six weeks, with some elevations of temperature and convulsions, chiefly on the right side, followed by transient right hemiplegia. Following each attack there were disturbances of speech, with a condition termed word-deafness, and the peculiar visual disturbances we are about to mention. The patient could see a chair which was in his way, but only avoided it after having once stumbled over it. Fire brought close to his eye did not frighten him. He touched it to find out what it was, and only then avoided it. He could see wine, but seemed not to know its use until it was brought to his lips.

There appeared to be no contraction of the field of vision, for objects brought from any side were immediately perceived. Fundi oculi were normal. The disturbance both of speech and vision remained for about ten days when they gradually disappeared, but after each such attack a number of words and visual images seemed to be permanently lost. The post-mortem examination revealed the diffuse changes in the brain commonly found in general paralysis.

In another case, after a paralytic attack the patient recognized some objects through the sense of vision, while he did not recognize others. Thus, he recognized his bed, fire, and bread, but not a needle, shoes, or his clothes. But (just as in the case of Munk's dogs) he learned to know a needle by its mere appearance after being taught what it was by means of other senses.

The last case I shall mention is one reported by Zacher,[2] in which a paralytic attack left the patient with difficulties of speech, and motor and sensory disturbances, and the same kind of visual symptoms. Though paralytics generally seize food very greedily, this patient left it untouched until put in his mouth. He was very fond of cigars, but he now took one in his hand and again laid it aside, apparently not knowing its use. These visual disturbances were present only a few days.

It is by no means easy to determine the exact character of the visual disturbances in the above-mentioned and similar cases. The difficulty is increased by the fact that in all of them there was a degree of mental weakness, and in some well-marked dementia. It is quite probable that in all of these instances there was some impairment of vision, and that impaired vision alone can produce somewhat similar disturbances seems to be proven by two cases of Wilbrand.[3] In both of these instances the patients became suddenly unable to recognize objects about them, their own houses, streets in which they resided, etc. They could not, therefore, find their way in the streets, though they continued to see. Both patients were sound mentally, and in each a homonymous lateral hemianopia was subsequently found.

In the above cases, also, blindness or impaired vision in parts of the retina is very probable. In the first case of Fürstner the manner of seizing an object, the constantly moving the head from side to side in trying to count, and overlooking some objects while counting others repeatedly, seem to point with great certainty to spots of retinal blindness. It is true that the patient was carefully examined by skilled physicians and that color blindness, hemianopia, etc., were excluded, but slight disturbances can be overlooked even on careful examination. This fact is well illustrated by a case of Wernicke[4] in which an eminent ophthalmologist could find nothing abnormal, though relative scotomas were afterward detected, certain parts of the retina being still sensitive to light, though the acuity of vision in some parts was diminished.

But if it could be determined that in all cases of so-called soul-blindness there is impairment of vision, this would not necessarily explain the complex of symptoms. The condition may, nevertheless, be found in them which Munk claims to be present in his dogs; that is, in addition to a degree of retinal blindness, and quite independent of the latter, a loss of cerebral visual images which in itself explains the symptoms.

There is, in fact, much which points toward the correctness of such an explanation. In many of these cases there were at the same time disturbances of speech, especially that condition termed word-deafness, where those peculiar conditions appear to be positively determined with reference to hearing whereof there is now question as to the sense of vision; for, in these instances, without having lost the sense of hearing the patients do not comprehend what they hear.

It is also a singular fact that in almost all cases of "soul-blindness" the left side of the brain was affected, which, as we have been taught by other clinical observations, seems to be the seat of the highest cerebral functions.

The existence of a condition termed word-blindness, where written and printed words cannot be read, a condition not infrequently found, and also present in some of the above cases, strengthens the belief that certain visual images may be lost while vision is retained. Yet it must be acknowledged that what has as yet been contributed is not sufficient to decide this difficult question, and its solution must be left, like that of some other questions with which we have dealt, to future investigations.

Diagnosis.—We must now consider the practical aspect of our subject, the value of the visual disturbances of which we have spoken, especially hemianopia, in diagnosis.

When carefully sought for hemianopia is not infrequently found in cerebral disease, especially in those cases where the disease is ushered in by an apoplectic attack. Hughlings Jackson[1] found hemianopia in quite a number of cases of hemiplegia, and Gowers[2] states that he never fails to find hemianopia in hemiplegics when he looks for it at an early period. But in the latter case this symptom has a local significance. A sudden hemiplegia is usually caused by a cerebral hemorrhage or the plugging of a vessel, conditions which produce a temporary paralyzing effect upon the entire brain, or at least upon one hemisphere. Hemianopia produced at such a time need not indicate any direct involvement of the visual centres. In the same way a hemorrhage in the occipital lobe may cause hemiplegia, though this part of the brain has no motor functions. It is these distant effects, produced by sudden lesions, which, when not properly estimated, bring confusion into the study of cerebral localization. The clinical manifestations, hemiplegia, aphasia, hemianopia, etc., which are present only a short time after an apoplectic attack, are usually valueless in assisting to localize lesions. Only permanent symptoms have a local significance.

If, now, hemianopia be a permanent symptom, it indicates that there is a lesion of some part of the visual apparatus, but it gives us no knowledge of its more exact locality. We have learned that lesions of the optic tracts, of the occipital lobes, and of the parts connecting the two, may cause hemianopia, and must now seek for other means to determine more precisely the seat of disease.

There are a few special symptoms which may be of value for this purpose. The first is the condition of the pupils. Disease of the occipital lobes has no influence on the contraction of the pupils. When both occipital lobes are destroyed, and there is complete blindness, the pupils continue to respond to light. But if the blindness be of peripheral origin, due to degeneration of the optic nerves or tracts, the pupils cease to respond to

[2] Brit. Med. Journal, November 24, 1877.

light. Nevertheless, in cases of hemianopia this difference in reaction of the pupils is of little consequence, because one-half of the retina is still sensitive, and the pupil will respond, no matter whether the injury to one-half of the visual apparatus be central or peripheral. But Wernicke believes that, even with these unfavorable conditions, with proper care and skill we can gain something from this symptom. This is to be done through allowing light to fall upon only one-half of the retina by means of proper apparatus. Wernicke mentions a case[1] where he censures himself for having neglected this means of arriving at a correct diagnosis. The case was one in which there was double hemianopia, therefore complete blindness. The pupils responded to light, and the diagnosis was, consequently, disease of both occipital lobes. The *post-mortem* revealed disease of only one occipital lobe. The second hemianopia was caused by the compression of the optic tract of the other side. Wernicke believed that he could have arrived at a correct diagnosis had he tested the pupils by throwing light upon only one-half of a retina at a time. On account of the difficulties and perhaps unreliability of such examinations we may be permitted to believe that they will never be of much practical value.

The ophthalmoscopic appearance of the optic disks may also assist us to distinguish peripheral from central disease. The object of the examination is to determine whether or not there is any atrophy of the optic nerves. Peripheral disease is more frequently and more quickly followed by such atrophy than central disease, so that the early appearance of discoloration of the disks makes the existence of peripheral disease probable.

These symptoms, then, though they have an absolute worth, are practically of little value. As in cerebral lesions elsewhere located we must base our diagnosis upon the history of the case and the whole complex of symptoms. The mention of two cases will serve for illustration.

The first, a man sixty-eight years of age, observing a defect of vision consulted an ophthalmologist, who found a left hemianopia. There was no other symptom at this time, and the patient continued to attend to his business until two weeks before I saw him, when his wife sent for the family physician, because there seemed to be some change in his mental condition, loss of memory, etc. When I saw him there was complete blindness in the left half of the field of vision, and the patient saw but very little in the right half; there was double hemianopia. There were no changes in the fundus of the eye and the pupils responded to light. There were no other localizing cerebral symptoms. His only other were mental symptoms. He was forgetful of recent occurrences, more emotional than normally, and was occasionally confused as to locality.

The diagnosis was, degenerative changes in both occipital lobes, probably due to thrombosis in the posterior cerebral arteries. The disease involved the visual apparatus of both sides. It was not a double peripheral lesion, or the pupils would not respond to light. It was not like the above case of Wernicke, in which one lesion (a tumor) destroyed one occipital lobe and compressed the opposite optic tract, because everything was opposed to the presence of an extensive lesion of this character. The mental symptoms indicated that the cortex was affected. From the fact that there were so few symptoms, we may judge that the cortex was directly involved in the lesion, and not indirectly affected by a large lesion in a distant part.

All above said only permits us to conclude that one occipital lobe is the seat of disease. It could not be denied that the hemianopia of one side might still be due to peripheral lesion. But it is probable that in the latter instance also the disease is central, not peripheral.

The second case, a man sixty-six years of age, has had right hemianopia since seven years ago. At that time he had a sudden seizure without loss of consciousness—he cannot recall details at this time—after which he was confined to bed for a month. He thinks that he was not paralyzed, but inasmuch as he was confined to his bed for a month at least, a hemiparesis was probably present. An examination by an ophthalmologist, made four months later, revealed a right hemianopia, which did not reach quite to the point of fixation. There was slight improvement within the next year; the field of vision of both eyes became a little larger.

Some months ago his vision again became suddenly worse, probably due to an attack of the same kind as the first one. At the present time there is a right hemianopia reaching, apparently, to the point of fixation, though, on account of the restless condition of the patient, its exact limits can not be determined with certainty. The pupils respond to light. The ophthalmoscopic appearance is normal. There are no other cerebral symptoms, but the patient says he is able to do far less mental work than before the last attack.

This patient has valvular disease. The diagnosis is embolism of the left posterior cerebral artery. But the diagnosis is only a probable one. It is based upon the probable extent of lesion, the absence of other localizing symptoms, and the mental impairment.

Bernhardt[1] reported a number of cases a few years ago, where, in addition to hemianopia, there were transient affection of sensation and motion, and occasional unilateral convulsions on the same side. The clinical picture in these cases suggested the presence of degenerative changes, especially in the surface of the brain, extending beyond the limit of the occipital lobes. They remind us of Westphal's case, where the autopsy revealed changes limited to the cortex.[2]

It is needless to speak further of individual cases. The above instances are sufficient to indicate how a diagnosis is arrived at, and they illustrate another fact, that the diagnosis is often problematical.

It may appear to one who has carefully read these papers that the laborious and diligent application, and the profound research which have been devoted to this subject, though they have done much to enrich scientific knowledge, have added little to our powers of curing disease and alleviating human suffering. And, at present, such a view has much to substantiate it, though the case of Wernicke and Hahn affords a brilliant illustration of what can already be done in cerebral surgery. But knowledge of cerebral localization is of very recent date. Advances are constantly being made, and it is only reasonable to believe that far more exact diagnoses will readily be made in the future. Therapeutic appliances are also becoming better understood and more valuable, and especially are radical surgical operations performed with a degree of safety not formerly dreamt of.

With such favorable indications before us we are not over bold when we venture to state that the knowledge of cerebral localization will yet be the source of great practical benefits to mankind, that it will ofttimes enable the physician to cure those diseases which are of all the most appalling, for they not only shorten life and entail great suffering, but also threaten the afflicted with the loss of reason.

Trichlorated Phenol in Erysipelas.—At a recent meeting of the Surgical Society of St. Petersburg, Dr. Papow communicated the results of his experience with this form of phenol as a local application in erysipelas. The author reached the conclusion that the drug arrests the development of, or destroys, the micro-organisms upon which the disease is supposed to depend. He advised its application in a ten-per-cent. solution, to be brushed over the diseased part and the adjacent skin.—*Gazette des Hôpitaux.*

HISTORY OF A CASE OF FISTULA IN ANO ACCOMPANIED WITH INCONTINENCE OF URINE OF SEVERAL YEARS' STANDING.

By MORRIS H. HENRY, M.A., M.D., LL.D.,

LATE SURGEON-IN-CHIEF OF THE NEW YORK STATE EMIGRANT HOSPITALS.

I BELIEVE in the records of clinical contributions that speak for themselves, written in such a way that they need little or no commentary to explain their meaning or add to their interest.

CASE.—Mrs. ——, about thirty years of age, married about ten years, in affluent circumstances, has children, is of full habit and to all outward appearance perfectly healthy. I was called to her by the advice of her medical attendant, at her summer home, some distance from New York, in June, 1883. She had been under the especial care of a New York physician during the summer of 1882, who made his home at a hotel in the immediate vicinity of her then country residence, but a short distance from New York. His "specialty" was diseases of women, and he was selected to attend her on that account. He made what he termed a "careful and thorough examination, and discovered an inflammation and ulceration of the os and cervix uteri, which accounted for all her distress and annoyances." Her main suffering, from her own account, was an intensely irritable condition of the bladder, constant desire to micturate, and severe pain in the rectum at every fœcal discharge. This had existed for more than ten years. She remained under the care of the gynecologist during the summer of 1881 without deriving much benefit. He was retained as her medical adviser, and was with her during her confinement, in the spring of 1882, with her fourth child. She made a good recovery from the birth of the child, but she still suffered from distress in the region of the rectum and the unceasing annoyance of incontinence of urine.

Such is the history of the case, in brief, afforded me June 26, 1883, when I was called to attend her. The local physician did all in his power to relieve her of pain until my arrival. She complained of a severe and intense throbbing pain in the region of the rectum, which had been steadily increasing during the past four days. The incontinence of urine had increased—she had, in fact, no control over the bladder. She had had no passage from the bowels for three days, and was averse to making any effort from fear of an increase of pain. The recent death of her father from fistula in ano and perineal abscesses added to her mental anxiety and suffering.

On examination I found a circumscribed, deep-seated inflammation, about three inches in diameter, on the left side of the rectum, the external border close in and involving the external sphincter of the rectum. There was a little oozing from the centre of the inflamed mass. I made a free incision and relieved her of about four ounces of pus. With the aid of a Sims speculum and a probe I discovered two fistulous openings in the rectum, one extending about two inches upward from the border of the anus, and the second not quite as far, both communicating with and terminating in the external abscess. By inserting a probe in each track the figure V was described, with the pointed end in the abscess. In deference to her wishes, owing to the appearance that morning of her menses, there was no further surgical interference that day. The wound was dressed with warm fomentations and the bowels relieved with mild enema. She was freed from the acute pain and the incontinence was lessened.

July 10, 1883, assisted by the local physician, who administered a little chloroform, I laid open the two fistulous tracks, cleansed the parts with a solution of labarraque, and dressed the wound with iodoform and vaseline. As soon as she had recovered from the effects of the chloroform—about three hours after the operation—ten grains of quinine and half a drachm of tincture of hyoscyamus was administered. A few hours of refreshing sleep soon followed. For the first time in many years she was able to retain her water many hours. The irritable condition of the bladder had ceased. The wound was dressed twice daily in the usual manner to induce healing from the lower surfaces.

July 17th.—The wound had entirely healed within the rectum, and a few days later it had done so along its whole course. There were no more painful or abnormal sensations about the rectum. The bowels yielded to gentle enema, and there was no longer any incontinence. I heard from her a few days ago—October, 1884. She was perfectly well.

I have now only to add that I believe this is not an isolated case. I record it with the hope of attracting attention to diseases of the rectum as a fruitful source of "diseases of the bladder and uterus" due to reflex causes. I have no doubt there are many persons suffering in a similar manner, without identification of the nature of the disease on the part of medical attendants.

581 FIFTH AVENUE, November, 1884.

NATURAL SULPHUR-WATERS, AND THEIR THERAPEUTICAL APPLICATION.

By HOWARD PINKNEY, M.D.,

NEW YORK.

DURING two summers spent in Europe visiting a few of the most noted spas, my attention was attracted to the large proportion of Americans there seeking relief for various ailments. I inquired of many why they came so far? also if they had ever tested the virtues of American springs? The usual answer was that "they had come by the advice of their physician," and that, with few exceptions, "they had never visited for treatment any springs at home." I have conversed with many of our eminent physicians and surgeons, and find that while they are quite familiar with the properties of European medicinal waters, they have paid but little attention to those in this country. Dr. Walton, in his work on the mineral springs of the United States and Canada, describes over one hundred and ninety sulphur springs in the United States; and Dr. Glover describes thirty sulphurous or sulphuretted spas in Europe. In comparing the analyses of these different sulphurous springs it will be found that all so-called springs contain certain ingredients in common, and differ mainly as to the proportion of these ingredients in each, and the temperature of the water as it issues from the sources. In order to satisfy myself as to some of the therapeutic effects of sulphurous waters, I spent three months at Sharon Springs. While there I had the good fortune to watch its effects in the following diseases, viz.: Rheumatism and gout, acute and chronic, eczema, psoriasis, nasopharyngeal catarrh, catarrhal inflammation of the Eustachian tube causing deafness, and one case of hemiplegia. In all the cases of rheumatism and gout seen before commencing the use of the waters, the secretions, viz.: urine, perspiration, and saliva, were excessively acid. After taking the baths and drinking the waters for a week or ten days, I found the secretions much less acid; after the fourth week of their use, in many cases little or no acid showed by the blue litmus paper test. In the cases of eczema the same result was shown. In one of two cases of psoriasis the eruption disappeared entirely after one course of baths. In the other, who only took the baths, etc., for two weeks, no improvement was perceptible. In the case of hemiplegia, where the baths and water were used most faithfully, I could detect no improvement in the paralyzed parts, although the general health and appetite improved.

As sulphuretted hydrogen gas is so freely generated in the bowels and expelled by the rectum, I at first thought that its introduction into the stomach, especially in cases

of dyspepsia, would be injurious. I therefore advised that the water should be first heated, in order to throw off the free sulphuretted hydrogen before being drunk; but, as many visitors, who, for years, had been in the habit of coming to Sharon, informed me that, whenever they had dyspepsia symptoms—especially acid stomach—they always found relief by taking a glass of the sulphur-water as it came from the spring, I could not doubt their testimony, and the following questions suggested themselves: Does sulphur-water prevent fermentation outside the body? If so, does it have the same effect in the stomach? To solve the first question, I made the following experiment: Taking two glass test-tubes of equal size, I partly filled one with sulphur-water taken directly from the spring. In the other I placed an equal amount of rain-water. To each I added an equal amount of ferment, composed of molasses and baker's yeast, corked and labelled each, and set them aside in a warm place.

On the following day, when I examined them, I found that the cork in the test-tube containing the rain-water had been forced out, and that the fluid in the tube was turbid and covered with a luxuriant growth of yeast plant. The other tube, containing the ferment and sulphur, appeared the same as when I set it aside—the cork was firmly in the tube, and no growth appeared on the surface of the liquid. I repeated this experiment with tank-water, and the water used at the table for drinking, with like results—the sulphur-water always arresting fermentation. I naturally came to the conclusion that if sulphur-water prevented fermentation outside of the body, it might have the same effect in the stomach. Now, if this theory is correct, may not some similar change take place in the blood of rheumatic and gouty patients, and account for, in a measure, the marked improvement in such cases from the use of the waters?

As I was anxious to make some investigations as to the effect of sulphur-spray upon inflamed mucous surfaces, I had an excellent opportunity of doing so, and also the effect of breathing and inhaling an atmosphere highly charged with sulphuretted hydrogen. In connection with the baths are three inhaling-rooms. In the first the sulphur-water is converted into a spray by means of compressed air, and so arranged that it can be applied directly to any part of the throat or nose. In the second room the water is converted into spray by steam and completely fills the apartment. In the third room the water, as it comes from the spring, is mechanically broken up and the sulphuretted hydrogen set free by a series of fountains. The air of this room is constantly charged with an excess of sulphuretted hydrogen and can be freely and safely inhaled. All the cases of catarrhal inflammation that I had an opportunity of watching received marked benefit from this mode of application. The beneficial effects I think result from the following causes: First, the steam spray softens and relaxes the inflamed mucous surfaces; second, the compressed air spray cleanses and stimulates to a healthy action the surfaces with which it comes in contact; third, the breathing of air charged with sulphuretted hydrogen gas has an anodyne and somewhat narcotic effect. Physicians who are in the habit of using the spray frequently have added to the sulphur some medication, as benzoic and boracic acids; some preparations of the pine, as the extract or oil made from the needles or leaves of the pine, such as are used so largely in Germany in similar affections. The object that I have in view in writing the above is, to stimulate a more thorough research into the medicinal properties of the almost numberless medicated springs in the United States, thereby enabling physicians intelligently to advise their patients in regard to the various springs, at the same time sparing them the many inconveniences of sea and continental travel, especially should they be lame or crippled.

24 East Forty-first Street.

Reports of Hospitals.

ST. LUKE'S HOSPITAL, NEW YORK.

Irrigation of Stomach for Chronic Gastritis.

Reported by SAMUEL T. KING, M.D., House Physician.

The almost uniform success that has been obtained during my term of service by irrigation of the stomach, or lavage, for chronic gastritis (gastric catarrh), is my apology for publishing the results of treatment in the following cases.

The method of lavage, as performed at the hospital, is very simple. The patient is instructed to take no breakfast. At about 10 A.M. the stomach-tube is introduced and the stomach is washed out several times by the aid of siphonage. The apparatus used consists, first, of a quite flexible rubber tube from one-third to one-half an inch in diameter, about twenty-eight inches in length, one end being freely open and the other closed, rounded, and with one oval aperture on each side; second, of an ordinary black rubber tube three feet long, attached by means of a short glass tube to the stomach-tube first mentioned; third, a small funnel. The temperature of the water used varies from 100° to 110° F. In two or three quarts of this water is dissolved a teaspoonful of borax. The amount of water tolerated is judged by the subjective sensation of fulness, and it varies considerably with each case. The stomach is washed out until the returning fluid becomes quite clear, usually three or four washings proving sufficient.

After introducing the tube a little beyond the root of the tongue, the patient is instructed to swallow, and at the same time the tube is pushed somewhat rapidly into the stomach. Occasionally at the first introduction there is considerable difficulty from retching, but by proper manipulation this may be readily overcome. After three or four introductions the patient himself will be able to introduce the tube.

The following are abbreviated reports of all the cases of chronic gastritis which have been treated by lavage during the past year.

Case I. (*Services of Drs. Beverley Robinson and Francis P. Kinnicutt.*)—Robert W——, seventeen years of age, native of the United States, errand boy, was admitted to the hospital November 9, 1883. Two years before entrance he first began to have pains in abdomen, and soon after vomiting began. Had no hæmatemesis. At time of entrance he was in a truly pitiable condition, his stomach rejecting nearly everything. He was rapidly emaciating. Skilled treatment by drugs had failed to relieve him. Upon entrance, physical examination revealed dilatation of the stomach. Lavage was immediately commenced, and for the first few days the boy was nourished entirely by nutritive enemata. On November 22d he was placed upon small quantities of pancreatized milk by the mouth, given at short intervals; and from that time his diet was gradually increased, with the exception of one interval of a few days, when there was a return of the vomiting, until he could eat any form of nitrogenous food, and, finally, any kind of food. During the treatment by lavage he was given several drugs to prevent emesis and putrefaction, but apparently without any especial benefit. Patient had no more vomiting after December 22d. The lavage was reduced to every other day January 20, 1884, and entirely discontinued at the end of another month. From January 1st until date of discharge, February 19th, patient gained eighteen pounds in weight. From that time to the present date, October 22d, there has been no return of gastric symptoms.

Case II. (*Service of Dr. George G. Wheelock.*)—Louisa H——, colored, thirty (?) years of age, a domestic, was admitted to the hospital March 15, 1884. For a month previous to entrance patient had been vomiting

after eating and had suffered epigastric pain and distress. On entrance there was anorexia and rather persistent vomiting, and she gave a distinctly phthisical history. Physical examination revealed very slight pulmonary changes. Having obtained no satisfactory results from medicinal treatment, April 22d the patient was ordered lavage every day and strictly milk diet. The gastric symptoms were entirely relieved, and on April 30th she was allowed some nitrogenous food. On May 10th, because of some irregularity in diet, she again began to vomit, and although two or three trials were afterward made to confine her to a restricted diet, she was unable to restrain her appetite for forbidden articles of food, and was therefore discharged June 3d, materially improved in her gastric symptoms.

Case III. (*Service of Dr. George G. Wheelock.*)—Catharine T——, forty-six years of age, married, a cook, was admitted to the hospital April 15, 1884. She has always been a hearty eater, and occasionally indulges in malt liquors. Three weeks before entrance she began to vomit a greenish (bilious?) material, and for the last week the vomiting has been persistent. Patient has sour eructations, vomiting of a sour fluid, and tenderness and sensitiveness over abdomen, especially in epigastric region. Bowels are constipated. Medicinal treatment failing to give relief, she was ordered lavage and milk diet. She was discharged June 11th, having entirely recovered from her gastric symptoms. May 22d was the date of the last vomiting.

Case IV. (*Service of Dr. George G. Wheelock.*)—Geraldine E——, colored, thirty-two years of age, married, a domestic, was admitted to the hospital April 28, 1884. She has had frequent vomiting and headaches. She often vomits large quantities, and at times particles of food which she had eaten four or five days previously. Upon entrance, physical examination revealed marked dilatation of the stomach. Lavage with the usual precautions was ordered, and patient was discharged cured May 31st. She was seen during the latter part of the summer, and at that time there had been no return of her gastric symptoms.

Case V. (*Service of Dr. Francis P. Kinnicutt.*)—Eugene F——, twenty-two years of age, single, native of the United States, a tinsmith, was admitted to the hospital June 25, 1884. For the past year he had suffered from eructations of gas and a sour fluid and constipation, and had obtained no relief from skilled medical treatment. Has lost but little flesh and strength. Under treatment by lavage, with pancreatized milk as diet, his gastric symptoms were markedly improved but not entirely relieved.

Case VI. (*Service of Dr. A. Brayton Ball.*)—Matilda N——, thirty-three years of age, dressmaker, was admitted to the hospital August 30, 1884. She was suffering from chronic bronchitis and asthma. She had also suffered from sour eructations and occasional vomiting for some time previous to entrance. Her cough ceased under treatment, but she suffered from alternating diarrhœa and constipation and her gastric symptoms persisted in spite of all treatment. September 24th she was ordered lavage without change in diet, and in the course of ten days she was entirely relieved from her gastric and intestinal symptoms, and has had no return at present writing, October 22d.

Salicylic Acid in Lupus Vulgaris.—In a case of lupus, in which the disease had already done much damage to the side of the nose, the cheeks, and the eyebrows, Dr. Marshall (*Algem. Wiener Med. Zeit.*) succeeded in healing the ulcer with salicylic acid. He employed an ointment containing 3 j. of the acid to ℥ j. of vaseline. The cicatrix obtained was flexible and smooth. Altogether the result of treatment was very gratifying, and the author warmly recommends the use of the drug in similar cases.

Progress of Medical Science.

Iodoform in Organic Disease of the Heart.—Professor Testa (*Giornale di Med. è Ter. di Messine*) has reported some observations made by him on the curative effect of iodoform in organic disease of the heart. He has studied the subject for several years, and has observed the effect of the drug in a number of cases. The remedy is not directed against the lesions themselves, but rather against the effects produced by them. He gives the drug in pill form every two hours, until one grain is taken during the day. Its most marked effect is to diminish the number of heart-beats, while it increases the arterial tension.

Calculus Impacted in the Ureter, and the Feasibility of Removing it by Surgical Operation.—Mr. Henry Morris, Surgeon to the Middlesex Hospital, London, discusses (*The American Journal of the Medical Sciences*) the feasibility of removing from the ureter an impacted calculus, which, if allowed to remain, will sooner or later surely cause destruction of the kidney, if not of life. He gives very fully the clinical history, diagnosis, and prognosis of these cases, and finally urges that a calculus impacted in the ureter sufficiently near the vesical orifice to be felt with the finger can with care and suitable instruments be extracted through an incision of the bladder wall without fear of wounding the peritoneum, or laying open the cavity of the bladder. He describes his method of operating as follows: Having rapidly dilated the urethra, if the patient be a female, or opened the urethra in the median line immediately in front of the prostate, if the patient be a male, the neck of the bladder should be passed by the index finger of the left hand, and a careful digital examination made of the bladder walls. If a hard fixed body be felt covered over by the bladder mucous membrane, at or near the orifice of one of the ureters, a gum lancet-shaped knife on a long slender shank should be introduced along the left index finger, and with it an incision should be made through the tissue covering the calculus. The knife should then be carefully withdrawn, and a slender scoop or curette, introduced along the index finger of the left hand, still retained within the bladder, should be employed for gently turning the calculus out of its bed. Mr. Morris urges that an exploration of the bladder should be made with the view of performing this operation on the ureter —1. In hydronephrotic or pyonephrotic enlargement of the kidney, associated with bladder symptoms, with the hope of re-establishing the natural drainage through the ureter. 2. Before nephrectomy is resorted to for hydronephrotic or pyonephrotic tumors, which have been opened or tapped through the loin without benefit. 3. Before nephrectomy is resorted to in cases of suspected renal calculus in which no renal tumor exists, and where, after digital exploration and puncture of the kidney through the loin, no stone is found. 4. In cases of sudden or rapid suppression of urine, or anuria, occurring after symptoms which have given rise to suspicion of stone in one or other kidney or both kidneys. A kidney which has undergone compensatory hypertrophy may become blocked by a calculus which has been forced by the superimposed urine in the lower end of the ureter, and which cannot pass the vesical orifice of the ureter. Such a kidney may be, probably is, the only one the patient has to depend on; and in this case death must ensue if the obstruction is not removed. If no stone can be felt through the bladder, life may yet be saved by giving a vent to the pent-up urine by lumbar nephrotomy.

A Case of Imperforate Rectum in which Lumbar Colotomy was Performed.—Dr. John H. Packard records a case of imperforate rectum in which lumbar colotomy was performed with an unsuccessful result. From his experience he is now of the opinion that in cases in which the object is to open the bowel with a

view not only to immediate relief, but to the subsequent establishment of the natural passage and closure of that artificially made, inguinal colotomy is the better operation. His preference for the operation in the loin was based upon a belief in its greater safety, as well as upon his familiarity with it as practised upon the adult. But the risk involved in opening the peritoneal cavity, as well as the somewhat greater difficulty of the operation, would seem to be outweighed by the advantage of far readier access to the cul-de-sac forming the terminal part of the gut, and by the better prospect of thus remedying the abnormal condition.—*The American Journal of the Medical Sciences.*

The Interval Treatment of Bronchitis.—In *The London Practitioner*, September, 1884, Dr. Drummond, of Rome, urges the importance of treatment in those patients who have just passed through an attack of bronchitis, and having no longer any definite complaints are apt to fancy themselves in perfect health. He says truly that the leading points to be observed in the management of the various forms of bronchial inflammation are, as a rule, sufficiently manifest and easy of application, so that when called in to such cases there is little need for hesitation in the choice of remedies. Such periods of attack are, of course, especially at the extremes of life, times of the greatest alarm, anxiety, and pressing danger to the patient, who is apt, however, to think that, when they have passed away, all is well again, and for this reason we commonly lose sight of him until another seizure compels him again to seek our aid. We know, however, that this is very far from being the case; that very often his condition in the interval is very critical; that the latent cause, of which the bronchitis is only a secondary consequence, is still present; that the interval is the period when really *curative* treatment is available, and is the most important part of the life-history of his disease. As time goes on, if no attempt is made to deal with the diseased condition to which the bronchitis is due, recurrences are more and more frequent; and if the patient is still exposed to the exciting cause, especially in a variable climate, they come to be taken as a mere matter of course, and serve to mark the winter exactly like the return of snow and fog. The patient is hardly ever well, and becomes habituated to a condition of permanent disablement; his power of resistance to weather changes is diminished, and a barometric sensitiveness to them is developed. In the background, steadily advancing, hidden lesions lurk; and increasing emphysema, heart dilation, lung collapse, interstitial lobular pneumonia, dilatation of the bronchi, and other changes progress, slowly but surely sapping the patient's strength, shortening the duration and diminishing the enjoyment of life; so that, although chronic bronchitis is, *per se*, attended with comparatively little danger to life, it none the less originates or aggravates other lesions, with which its clinical history is interwoven, and often in their nature more perilous than itself. As regards the nature of the interval treatment, it must of course vary in different cases, according to the individuality of the patient. General measures, proper hygiene, and such medicines as may tend to improve the patient's constitution are all indicated, and need not be enumerated here.

Treatment of Malignant Pustule by Cruciform Incisions and Cauterization.—Dr. Barberini writes to the *Rivista Clinica e Terapeutica* for September, 1884, giving an account of two cases of recovery from malignant pustule. The first case was that of a herder, forty years of age, of fair general health. On the left side of the lower lip there was a small black spot, the size of a centime, slightly elevated, and surrounded by an inflamed area, which he said appeared the day before as a little vesicle exuding a little water when scratched. The tissues beneath the black spot were very painful upon the slightest touch, and the lymphatics of the part were swollen and cordlike. The patient's temperature was 103° F. Fifteen grains of sulphate of quinine were given at once, and two elliptical incisions were made through the inflamed zone at about $\frac{1}{10}$ inch distance from the blackened eschar, the enclosed parts being excised. The wound was then cauterized with strong carbolic acid (eighty-five per cent.). There was but little hemorrhage, but the patient fell into a state of collapse almost immediately. The case seemed hopeless, but quinine and broths were prescribed, and after thirty-six hours the patient began to show signs of consciousness and progressed slowly to full recovery. The second case was very similar to the first. The diagnosis of malignant pustule was undoubted. The elliptical excision and cauterization were practised as in the first case, with equally good results.

The Treatment of Hemorrhoids.—Professor Verneuil recommends cold local applications and mild laxatives in the treatment of slight cases of hemorrhoids. For the more severe cases he employs forced dilatation. Hemorrhoids are caused, he says, by a strangulation of the superior mesenteric veins which traverse the muscular wall of the rectum. This strangulation gives rise to the formation of the venous tumors, precisely as varicose veins are occasioned by constriction from the ring of the soleus muscle. If now the muscular contracture be overcome the venous circulation is restored and the hemorrhoidal tumors disappear. In order to insure success the dilatation should not be attempted with the fingers, but should be accomplished by means of a speculum. By means of this instrumental dilatation the author asserts that hemorrhoids may be radically cured within a week without the use of the knife.—*Revue Médicale*, September 13, 1884.

Recovery from a Punctured Wound of the Heart.—An old woman, suffering from suicidal mania, was observed one evening to become suddenly pale, falling back upon the bed, with the features convulsed, the pupils widely dilated, and the head rolling rhythmically from side to side. The pulse was very small, almost imperceptible, and there was almost complete paralysis on the left side and paresis on the right. There was also vomiting. On searching for the cause it was found that the patient had stabbed herself with a shawl-pin. The pin had entered the chest at the apex of the heart, and had passed inward and a little downward for a distance of three and one-fourth inches. The instrument was withdrawn, and under the influence of stimulants the heart recovered its normal action. For some time there was dyspnœa, and the patient experienced sharp pains in the precordial region, but at the end of ninety minutes all these symptoms, as well as the paralysis, had disappeared. The patient slept tranquilly that night, and made a perfect recovery.—*Gazette des Hôpitaux*, No. 100, 1884.

Colotomy.—A retrospect of the operation of colotomy appears in the October number of *The American Journal of the Medical Sciences* from the pen of Dr. Batt, of Phœnixville, Pa. A surgeon who subscribes to the doctrine that an artifical anus should not be made in the case of imperforate anus, is not justified in doing so on any principle of morality, since upon him rests an imperative obligation to employ to the utmost of his ability the means placed at his command for the relief of human suffering and the prolongation of human life. When we likewise consider of what vast importance is the prolongation of life in a human adult, and how vast may be the concerns which hang upon such an event, we find the same imperative duty no less binding. To obviate death from over-distention of the bowels, which is one of the most painful and distressing terminations of life, colotomy will be justifiable under conditions of the greatest gravity; and may be indicated in any obstructive complication of the lower bowel which has passed beyond the power of local remedies, and in which a judicious trial of medical treatment has failed to afford relief. Mr.

Phillips, of London, tells us that one case of intestinal obstruction occurs in every one hundred deaths, and from 139 cases of obstruction which he collected, in which surgical aid was not given, 133 proved fatal. The fact that such a terrible fatality as this should exist, and an operation affording the advantages of colotomy be unperformed, must ever be a shadow upon the honor of modern surgery. Statistics are presented which show most conclusively that the dangers of the operation are very few, and that the number of recoveries depends very greatly upon the nature of the affection for which it is performed.

The Prevention of Hernia after Laparotomy.—In a communication addressed to the *Centralblatt für Chirurgie*, No. 35, 1884, Dr. Hagen-Torn writes that in a recent ovariotomy performed by him, the incision passed accidentally partly through the rectus muscle and partly in the linea alba. Five months later he saw the patient, and found that the cicatrix in the muscle was firm, but that in the linea alba had yielded, giving rise to a hernia. The text-books usually advise that the incision be made in the linea alba, but the writer, basing his opinion upon his experience in this case, believes that the liability to hernia after laparotomy would be averted were the incision practised entirely in the rectus muscle. He thinks, also, that healing by first intention would be favored by reason of the greater thickness of the muscular tissue.

Stricture of the Œsophagus from Muscular Hypertrophy.—Dr. Ruppert relates in the *Gazeta Lekarska*, No. 17, 1884, the case of a young man who suffered from a gradually increasing stricture of the œsophagus. A diagnosis of carcinoma was made, and gastrotomy was advised. The patient refused to submit to the operation, and died of starvation. At the autopsy it was found that the stricture was caused entirely by hypertrophied muscular tissue. The most careful microscopical examination failed to discover any trace of cancer, the thickened œsophageal walls consisting of connective tissue and muscular fibres in a state of fatty degeneration.

Resorcin in Laryngeal Affections.—Dr. J. Andeer speaks very highly of the value of resorcin in the treatment of affections of the larynx. He says that this remedy has not only the advantage of thoroughly disinfecting instruments without rusting them, but it also possesses the valuable property of producing anæsthesia of the parts with which it comes in contact. A weak solution acts as an astringent, a concentrated one as a caustic, with this peculiarity, however, that it never occasions cicatrices, but simply promotes the growth of new epithelium. This renders it specially applicable to the treatment of ulcerations of the mucous membrane. The author states that really surprising results are obtained by the use of resorcin in hyperplasias, in aphonia of long duration, and in other laryngeal diseases. In tubercular ulcerations it serves to moderate the cough and quiet the pain.—*Revue Mensuelle de Laryngologie, d'Otologie et de Rhinologie*, September, 1884.

Aphasia from Indigestion.—Several cases of reflex nervous troubles, caused by digestive disturbances in children, are related in the *Journal de Médecine et de Chirurgie Pratiques* for September, 1884. A little girl, three years old, lost all power of speech, or even of making a sound beyond an exclamation of pain when pinched. This state continued for two hours, but ceased immediately upon an attack of vomiting, in which a quantity of food and several unbroken cherries were thrown off. A little boy was seized during the night with an attack of acute indigestion, and the next morning was aphasic and in a soporific condition. He slowly recovered the power of articulation toward the end of that day. In another case a young girl of nine years was suddenly seized with heat of the head and flushings, alternating with pallor of the face. Then she became aphasic, but recovered the power of speech in about an hour after having vomited undigested the meal taken the evening previous. Fraenkel has observed a case of hemiplegia due to indigestion. A girl, four years of age, was seized during dinner with vomiting and complete loss of consciousness. The physician thought that the case was one of alcoholic poisoning, although the mother affirmed that the child had taken but a very small quantity of wine. In about half an hour consciousness returned, and then it was seen that the right upper and lower extremities were paralyzed, both motion and sensibility being lost. This disappeared gradually, and the following morning the child was perfectly well.

Oleate of Chloral Compound in Pruritus.—A recent writer (*St. Louis Medical Journal*) has had an oleate of chloral made, which he claims to have used with much success in pruritus anus, eczema, and other affections associated with much itching. The compound consists of one drachm each of camphor and chloral and one ounce of oleic acid, thoroughly mixed together. Camphor and chloral in equal parts, forming a liquid, has long been known as a valuable remedy in cases where local anæsthesia of the cutaneous nerves is desired, and has been employed in neuralgias and pruritus. The addition of the oleic acid will undoubtedly increase the penetrating power of the mixture. It may thus be found useful in allaying the itching, while other means are employed to secure permanent relief.

Treatment of True Pneumonia by the Cold Bath.—Two communications have been recently sent to the *Gazette des Hôpitaux* by Dr. Chaumier, in which he strongly condemns the old treatment of pneumonia by drugs, blisters, emetics, and bleeding. The author claims that statistics prove pneumonia to be more curable without drugs than with them, and that children always recover from pneumonia when drugs are withheld. He used the cold-bath treatment in fourteen children, all of whom recovered. His observations lead him to conclude that there is no danger from the bath in any stage of the disease. He gives a bath of ten minutes' duration, at from 82° to 90°, every two or three hours to an adult, and two or three times a day to a child. Each bath produces a lowering of the temperature of from two to three degrees, of the pulse from ten to thirty-two beats, and of the respiration from six to fourteen per minute. The *bruit de souffle* produced by the fever disappears, dyspnœa is decreased, and there is less thirst. The author is inclined to think that mortality may be lessened by the use of the cold bath, although he is ready to admit that his own observations concerned such cases only as would doubtless have recovered without treatment.

The Etiology of Convulsions in Children.—Children, as is well known, are far more prone to convulsions than grown persons. According to Dr. Kjellberg (*Schmidt's Jahrbücher*), this is due not to any increased irritability in the motor or sensory tracts or in the reflex centres, but to the fact that the brain is unable to exercise any controlling influence upon the reflex centres. Convulsions which occur at the commencement or during the course of any acute disease through direct central irritation are symptomatic. Those which are excited reflexly by irritation of the sensory nerve-endings are sympathetic. Symptomatic convulsions are due in part to disturbances in the circulation and in part to changes in the blood. Among the disturbances in the circulation, the most common is a rapidly produced cerebral anæmia. This may be caused by hemorrhage, a rapid waste of the animal fluids, or arterial spasm. In other cases it is due to cerebral compression or anatomical changes in the brain, such as extravasation of blood, tumors, softening, etc. Hyperæmia may also cause convulsions indirectly. When an excess of blood is carried to the brain the cerebro-spinal fluid in the perivascular spaces cannot yield, but makes pressure on the smaller capillaries, whereby they are emptied of their blood, and the

real condition is then anæmia of the brain. The action of venous stasis is very similar in depriving the brain of its necessary supply of arterial blood. There are often changes in the blood at the same time with these circulatory disturbances. An elevated temperature is one of the most potent of these causes, as by it the irritability of the nerve-elements is increased. The quality of the blood may be impaired also by the introduction of poisons, either those introduced from without or those formed in the tissues of the body itself. In this category belongs also the change in the milk of nursing-women induced by violent emotion. Sympathetic convulsions may be excited by almost any irritation of the sensory nerve-endings, in consequence either of increased irritability of the nerves or of diminished power of the reflex controlling centres. In regard to the presence of worms in the intestinal canal, the author admits that this may be a cause of convulsions, but insists upon the necessity of a search for other causes, since worms may be present and yet have nothing to do with the convulsions. He believes also that dentition may be of etiological importance, and does not admit as valid the objections of those who say that this is a physiological process and therefore incapable of producing morbid symptoms. He does not doubt the fact of an hereditary predisposition to convulsions in certain families, but admits his inability to explain it.

The Action of Hypnotics on the Cerebral Circulation.—Drs. Bergesio and Musso, having a patient who had lost a portion of the calvarium, were enabled to make observations on the circulation in the brain. They confirmed the view that the brain is anæmic during sleep. Paraldehyde gave the same result as natural sleep. Morphia and alcohol caused endocranial congestion. The authors remark that the hypnotic effects of these drugs do not depend upon the changes they cause in the blood-pressure, but upon some more intimate modification, perhaps of a chemical nature, of the cells of the cerebral cortex.—*London Medical Record*, October 15, 1884.

Experimental Diphtheria.—In a series of experiments Cohnheim and Litten, by temporarily shutting off the blood supply, produced in the respective tissues changes in many respects similar to diphtheria. Necrosis by coagulation (Weigert) was a constant result. Dr. Heubner, following up these researches, produced a local diphtheria, not by the ordinary method of cauterizing the mucous membrane, but by temporarily interrupting the blood-current. His experiments were made on the bladders of rabbits, the neck of the bladder being tightly ligatured with a silk thread for two hours. On the succeeding days the alterations produced on the vesical mucous membrane were carefully studied. On the first day, these alterations consisted in an intense hemorrhagic œdema of the mucous membrane, the epithelium being raised and tumid. On the second day, there was a solid coagulated exudation. On the third day, true diphtheritic patches were found on the mucous membrane. Still later was formed a "necrosis from coagulation" of the epithelium, and of the mucous and submucous tissues. Microscopically, this deposit, diphtheritic membrane, was seen to be morphologically identical with the deposits observed in diphtheria, following scarlatina, and in epidemic dysentery. This artificial diphtheria, then, is produced by the combination of grave inflammation with necrosis. That in the diphtheritic parts the circulation of blood existed, even shortly before death, the author was able to demonstrate by the auto-injection of the vessels, like that which takes place in a very conspicuous manner in artificial pustular infection, in most evident degree, by means of the coloration of the bacilli. In man, local croup may be caused by spasm of the capillaries of the mucous membrane, lasting about two hours, the capillaries then again becoming pervious to the blood. Such a transitory interruption of the circulation may happen even from the pressure of a swollen tonsil on the vessel. The diphtheria artificially produced by the author was not transmissible by inoculation in healthy animals. In the second part of his work, Heubner seeks to establish an artificial synthesis between local diphtheria and general infection. To this end he first inoculated animals in whom the mucous membrane was affected by local diphtheria, with pustular virus, and found an excessive accumulation of bacilli in the affected parts, but only in the interior of the vessels, and never outside them. Afterward he inoculated animals, which were made to contract a local diphtheria, with diphtheritic masses from a man affected by grave diphtheria; the animals presented splenic tumor, hemorrhage of the serous membranes, and died after two or three days with symptoms of acute general infection. Microscopic examination of the patches showed in the affected vessels of the mucous membrane certain bacilli, partly disposed in groups, partly distributed in diplococci, partly as chains of four links. The same result was obtained with inoculation of scarlatinal diphtheria. However, the author affirms absolutely that the bacilli found do not represent the diphtheritic virus. If this were so, they must have been found also in the man in the vessels of the affected mucous membrane. That, however, the author has never succeeded in finding, although he has examined a long series of sections of the uvula. And for general infection there is no need of special diphtheritic microphytes. The author recalls the researches made to produce sepsis by the inoculation of the oral liquid of different men, sick and healthy (Vulpian). The micro-organisms found in the diphtheritic masses of the oral cavity are consecutive to the disease and not *vice versa*. Therefore, as the author believes, the virus of human diphtheria has not yet been found to be constituted of an organized material.

Faradization in Obstetric Practice.—Dr. Tipiakoff describes the results of faradization as used in Professor A. M. Makëëff's obstetric clinic in Moscow (*Vratch*, Nos. 24 and 25, 1884). The conclusions at which the author arrives are these: 1. The electric current is a powerful as well as a simple and safe means of inducing uterine contractions; hence it is indicated for inducing abortion or premature labor, also in cases of uterine atony and *post-partum* hemorrhage. 2. Since the strength of the uterine contractions bears on the rapidity of dilatation of the os, faradization is indicated wherever a more rapid dilatation of the os is desirable; as, for instance, in cases of hemorrhage depending on placenta prævia or accompanying abortion with an irregular course. 3. In the puerperal period faradization favors a more regular and complete involution of the womb. 4. In cases of puerperal endometritis, faradization brings about continuous uniform uterine contractions, and in this way assists the organ to expel decomposed lochia; that is, it prevents the possibility of self-infection, and soothes the paroxysmatic pain which causes so great a discomfort to the patient.

Affections of the Liver in Inherited Syphilis.—In the *Archives Générales de Médecine* Dr. Barthélemy discusses the question of disease of the liver in connection with inherited syphilis, by the light of thirty-two cases, which he has collected from various sources, many being from English publications. From a study of these cases the author has arrived at the following conclusions. Inherited syphilis, like the acquired form, may give rise to four kinds of lesion of the liver: 1, a congestive form; 2, diffuse interstitial hepatitis; a cirrhosis rather hypertrophic than atrophic; 3, gummata; 4, amyloid disease. Affections of the liver are much more frequent than they are supposed to be, bearing in mind the number of subjects of inherited syphilis who survive. Judging from the frequence of affections of the liver, and from the fact that the cure or death of the patient may depend on whether specific treatment is adopted or not, the author thinks that the question of inherited syphilis should be borne in mind in every case of hepatic disease where the cause is

doubtful, or the course unusual, either in respect of the age of the patient, or in the absence of a history capable of explaining the malady. For, after alcoholism and malaria, inherited syphilis is, in the author's opinion, the most frequent cause of disease of the liver, not only in early but in later life.

Hache on the Pathology of Cystitis.—Dr. Hache thinks that lesions of the bladder and irritation applied directly to its wall and mucous membrane do not constitute a necessary and sufficient cause of cystitis, except in case of vesical tuberculosis, or of the presence of a rough and irregularly shaped foreign body. The causes capable by themselves of constantly determining inflammation of the bladder are very rare. Beyond tubercular cystitis, and other forms of cystitis due to some general morbid condition—as, for instance, those of rheumatic, gouty, and infective nature, which are not of frequent occurrence—there cannot be included in the above category scarcely any save severe accidental or surgical traumatisms of the bladder, and too sudden and complete evacuation of this organ after over-distention. Gonorrhœal urethritis does not often give rise to cystitis, except under the influence of some occasional cause or in a predisposed subject. Most of the predisposing causes act quite simply by determining a more or less persistent congestion of the bladder; others have a more or less obscure mode of action, although their influence is very decided. Chief among these predisposing causes are the tubercular, rheumatic, and gouty diatheses. These predisposing causes may sometimes become exciting causes by increase, extension, or repetition of their action, or through association with that of other causes of the same group. These latter causes are congestion and slight inflammation of neighboring organs, especially in the female; tumors, calculi, and foreign bodies in the bladder; incomplete retention of urine, with or without distention; habitual resistance to the needs of micturating, and all the causes of dysuria and functional over-activity of the bladder; stricture and foreign bodies in the urethra, hypertrophy of the prostate, etc. Finally, the part of exciting cause is more especially played by sudden and complete retention, by cold, by catheterism or exploration of the bladder. The latter cause can act only on a bladder predisposed by the presence of a tumor or calculus; the other two causes are more active, and may even by themselves suffice to excite an attack of cystitis. Dr. Hache's study of the pathogeny of cystitis has led him to insist on the importance of congestion and diathesic influences, especially the tubercular diathesis, and on the relatively limited part played by lesions of the urethra and prostate.—*Revue de Chirurgie.*

Hydrate of Thierpvlene.—This substance, which has been discovered by M. Boursier, can be extracted by distillation from the buds of several sorts of pine. The fluid is saturated with oxygen, and contains a large proportion of ozone. According to the author (*Rev. de Thérap. Médico-Chir.*, No. 15, 1884) it possesses very marked antiseptic and deodorizing properties, and can be used for dressing wounds and for painting the throat in diphtheria. The vaporized fluid has a smell of turpentine, and is said to be an efficient agent for the disinfection of rooms.

Lithotrity Extraordinary.—Dr. R. Cran, of Upper Luckimpore, Assam, states that stone is not so rare a disease in Assam as Dr. Partridge thinks. He relates the death of a patient, "after a most peculiar operation, which I shall describe as showing the advanced state of surgery to which they have attained. The priest, having placed the patient on his back, raised well the anterior wall of the abdomen, placed a stone on one side of it, and belabored the other with a second stone, desisting when the calculus was supposed to have been crushed. The patient died a few days after the operation. This was told me by the first man I operated on."—*Indian Medical Journal.*

Experiments on the Supra-renal Capsule.—M. Tizzoni, the Italian pathologist, has performed during the past year an interesting series of experiments on the supra-renal body. In order to avoid unnecessary sacrifice of life, the author studied the best methods of removing the supra-renal capsules without damage to the surrounding structures and with the infliction of the least possible injury to the system at large. After having made a small incision in the lumbar region at the level of the adrenal body, the parenchyma of the capsule was lacerated and its ablation practised, strict antiseptic precautions being observed. On the right side the neighboring vena cava inferior rendered the operation of extirpation difficult. For his experiments Tizzoni generally made use of rabbits weighing only about a kilogramme each, because in this circumstance the muscular mass of the lumbar region was but little developed, and so the operation was facilitated. When the animals succumbed as the result of the operative procedure, death was not due to the nervous accidents signalized by Brown-Séquard, but was caused by subcutaneous and intermuscular suppuration infiltrating the neighborhood of the wound. The majority of the animals which exhibited contracture of one or other of the front or hind limbs recovered, and it was only rarely that paralysis and death followed the appearance of the spastic contraction. The necropsy revealed in such cases the presence of an exudation about the meninges of the spinal cord and a softening of the spinal marrow without any demonstrable direct connection of the lesion of the supra-renal capsule with that of the nervous centres. Outside these compli cations—which may be regarded as quite exceptional—the operation was generally followed by no grave accidents; the animal, if the etherization were not too powerful, gave signs of pain only when the adrenal capsule was seized and lacerated. If this body, instead of being completely removed, were allowed to remain in the cavity of the abdomen (of course, after laceration of the capsule), the healing was much more rapidly effected; and if, some days later, the animal were killed, not a trace of the lacerated parenchyma of the supra-renal capsule could be detected; complete absorption of the essential elements appeared to have taken place. Then, according to Tizzoni, the supra-renal body is absorbed without giving rise to any phenomena such as might be interpreted to be of the nature of blood-poisoning, so that the adrenal capsule contains no organic poison; and if by treating the organ with various chemical reagents a poison be obtained, one may affirm that it is not produced during life, and consequently the poison must be due to cadaveric decomposition. A certain time after the extirpation of the capsule there commences to appear a brownish discoloration of the nose, as if the animal had been plunged in charcoal powder after having drank some liquid. Some small blackish linear markings also may be found scattered here and there over the mouth and nasal fossæ. The mucous membranes of these regions seem at first to be intact, but at the end of some days they become dotted with minute spots of the color of tobacco; the minute areas become circular as they enlarge, and by coalescence a bronzed surface of considerable extent and of a uniform tint is formed, and reaches its maximum intensity about the sixtieth day after the operation of removal or laceration of the supra-renal capsule. A remarkable circumstance is mentioned by the Italian observer, which is to the effect that the destruction of one capsule only brings about unilateral pigmentation of that side of the body on which the operation was performed. Tizzoni further states that the various elements of the supra-renal capsule may be reconstructed. He observed one case, one hundred and forty-four days after the supra-renal body had been almost totally destroyed, in which this regeneration had taken place. He does not seek to explain the mode of production of the bronzing which he observed.—*London Lancet*, September 27, 1884.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, November 15, 1884.

THE UNITED STATES COMMISSIONER OF EDUCATION ON MEDICAL EDUCATION AND PRACTICE.

THE Report of the Commissioner of Education for 1882–83 contains an unusually elaborate review of the progress of medical education, written in a critical but at the same time candid and intelligent spirit. The views expressed and suggestions made are in harmony with those which have appeared in the editorial columns of THE MEDICAL RECORD during the past few years. Coming from a gentleman like General Eaton, however, who has made the subject of education a special study for many years, they have a fresh interest and force.

A review of the condition of medical education during and since colonial times is given, and the gradual evolution of the present system of making doctors described. It is shown that although we have now vastly better means of educating medical students than formerly, yet we are at present suffering from the consequences of a long-continued and irrational freedom in the matter of graduating and licensing medical men.

The old idea, that a physician should be a man of learning and letters as well as of art, having been dissipated, and all but a few restrications upon education and licensing having ceased to exist, "the past fifteen years," says the report, "shows a very rapid increase in the number of medical schools and students."

"In plain English," continues General Eaton, "the time has now come (the profession being so crowded and the increase of candidates for employment being so much greater in proportion than the increase of population) when the medical student pays to the medical college money for which he receives no calculable equivalent; he asks for bread and receives a stone. The really capable graduate is jostled, crowded, shouted down, and trampled upon by a horde of unwieldy behemoths, who not only intercept most of the work that he only is able to do satisfactorily, but who supplement their scant incomes by arts and devices that his nature and training forbid him to join in. Having overcrowded all other departments of medical employment, many of these physicians by the grace of a diploma have lately taken up the work of opening and conducting medical colleges, much to the wrath and confusion of the older schools, who would dearly like to retain their monopoly of oversupplying the market with medical 'spring chickens.' The position assumed by these older schools is exquisitely illogical: they do not like to establish effectual entrance examinations (which might force some candidates to defer the study of anatomy and chemistry until they had mastered the simpler mysteries of reading and writing) because they do not want to limit the number of doctors by artificial regulations. This phrase, quoted from a recent address by a widely known and much respected medical teacher and author, teaches us that artificial regulations mean all rules or usages that may or can hinder any young white man from paying money twice over for the privilege of hearing the same course of lectures during two courses of instruction. The regulations that forbid the faculty from receiving the money of a white *woman* or that of a *black* man, we learn by inference, are not artificial."

The report begins with some comparative statistics showing the number of schools of medicine, dentistry, and pharmacy in this country since 1873.

	1873.	1874.	1875.	1876.	1877.	1878.	1879.	1880.	1881.	1882.[1]
Number of institutions...	94	99	106	102	106	106	114	120	126	134
Number of instructors...	1,148	1,121	1,172	1,201	1,278	1,337	1,495	1,660	1,746	1,946
Number of students...	8,681	9,095	9,971	10,143	11,225	11,830	13,321	14,006	14,536	15,151

Another valuable table shows the present condition of these same schools:

	Number of schools.	Corps of instruction.	Students.			Libraries.	
			Present number.	Present students who are graduate students.	Graduates at the commencement of 1882.	Number of volumes.	Increase in the last school year.
Medical and surgical:							
Regular	80	1,314	10,523	851	3,617	40,057	1,011
Eclectic	10	100	907	80	312	1,400	200
Homœopathic	11	188	1,309	64	437	4,530	29
Dental	18	276	820	24	323	6,084	23
Pharmaceutical	15	68	1,592	2	427	5,695	263
Grand total	134	1,946	15,151	1,021	5,116	57,766	1,526

	Property, income, etc.			
	Value of grounds, buildings, and apparatus.	Amount of productive funds.	Income from productive funds.	Receipts for the last year from tuition and other fees.
Medical and surgical:				
Regular	$2,713,800	$321,283	$18,209	$456,600
Eclectic	228,600	3,000	.....	62,897
Homœopathic	310,000	.....	.....	40,500
Dental	87,000	.....	1,568	74,000
Pharmaceutical	180,200	6,800	372	38,219
Grand total	$3,519,600	$331,083	$20,149	$672,216

Quoting this same "medical professor and author" further in denunciation of the many new and small colleges which are springing up all over the country, the report adds: "Denunciations like the foregoing are of little value, for they accomplish nothing; when analyzed dispassionately they are reduced to complaints that newer competitors are underselling 'the old and well-known stands.' Of course the customers at the cheaper shops will get an article of inferior quality; that also is a 'law' of trade." We cannot agree, however, here with

the opinion further expressed that closing up the small and cheap colleges would do no good. It is only true that they will not close until there arises a wider demand for the best educated doctors.
